#### Abstract

As the second phase of our study of the atmospheric ozone formation potentials of constituents of aluminum rolling mill emissions, a series of environmental chamber experiments and computer model simulations were carried out to assess the atmospheric ozone formation potentials of the selected cycloalkanes hexyl cyclohexane and octyl cyclohexane. The experiments consisted of determining the effects on NO oxidation, ozone formation and OH radical levels when adding the compounds to varying simulated model photochemical smog systems. The chamber experiments employed both blacklight and xenon arc light sources. These data supplemented similar experiments carried out previously on $\mathrm{C}_{12}-\mathrm{C}_{16}$ normal alkanes. Like the $\mathrm{C}_{\geq 12}$ normal alkanes, these cycloalkanes were found to be strong inhibitors of radical levels, inhibited rates of NO oxidation and $\mathrm{O}_{3}$ formation in experiments that are sensitive to radical effects, but had only relatively small effects on $\mathrm{O}_{3}$ in experiments more representative of atmospheric conditions.

Model simulations using the recently developed SAPRC-99 atmospheric chemical mechanism was gave good simulations of the results of the $\mathrm{C}_{\geq 12}$ normal and cyclic alkane data obtained in both phases of this project. This mechanism was then used to calculate that impacts of these compounds on ozone formation in a one day box model scenarios representing various urban areas around the United States. These were compared with ozone impacts calculated for ethane, the compound that has been used by the EPA to determine "negligible" ozone reactivity for regulatory exemption purposes. The ozone impacts for the $\mathrm{C}_{\geq 12}$ alkanes were found to be highly dependent on scenario conditions and how the ozone impact was quantified. In most cases the $\mathrm{C}_{\geq 12}$ alkane ozone impacts on a mass basis were less than $25 \%$ those of the mixture representing VOCs from all sources, but the impacts relative to ethane varied greatly. In general, the impacts of the $\mathrm{C}_{\geq 12}$ alkanes on maximum 8-hour average ozone levels were found to less than those of ethane under most conditions, while their impacts on peak ozone yields tend to be greater than ethane, except for the lowest $\mathrm{NO}_{\mathrm{x}}$ scenarios. However, the results are highly variable and dependent on other scenario conditions besides $\mathrm{NO}_{x}$.

## ACKNOWLEDGEMENTS

The authors acknowledge Mr. Dennis Fitz for assistance in administering this program, Mr. Kurt Bumiller for assistance in carrying out the environmental chamber experiments, and Dr. Roger Atkinson for helpful discussions. We also thank Dr Roger Atkinson for kindly providing the methyl nitrite used in the kinetic experiments carried out for this project.

This work was funded by the Aluminum Association through contract number AA 1345. However, the opinions and conclusions expressed in this report are entirely those of the primary author, Dr. William P. L. Carter. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

## INTRODUCTION

Ozone in photochemical smog is formed from the gas-phase reactions of volatile organic compounds (VOCs) and oxides of nitrogen $\left(\mathrm{NO}_{\mathrm{x}}\right)$ in sunlight. Although Houston and Los Angeles currently have the worst ozone problems in the United States, other areas of the country also have episodes where ozone exceeds the federal air quality standard. Ozone control strategies in the past have focused primarily on VOC controls, though the importance of $\mathrm{NO}_{\mathrm{x}}$ control has become recognized in recent years. VOC and $\mathrm{NO}_{\mathrm{x}}$ controls have differing effects on ozone formation. $\mathrm{NO}_{\mathrm{x}}$ is required for ozone formation, and if the levels of $\mathrm{NO}_{x}$ are low compared to the levels of reactive VOCs, then changing VOC emissions will have relatively little effect on ozone. Since $\mathrm{NO}_{\mathrm{x}}$ is removed from the atmosphere more rapidly than VOCs, ozone in areas far downwind from the primary sources tend to be more $\mathrm{NO}_{\mathrm{x}}$ limited, and thus less responsive to VOC controls. VOC controls tend to reduce the rate that $\mathrm{O}_{3}$ is formed when $\mathrm{NO}_{\mathrm{x}}$ is present, so VOC controls are the most beneficial in reducing $\mathrm{O}_{3}$ in the urban source areas, where $\mathrm{NO}_{x}$ is relatively plentiful, and where $\mathrm{O}_{3}$ yields are determined primarily by how rapidly it is being formed. Because of this, any comprehensive ozone control strategy should involve reduction of emissions of both $\mathrm{NO}_{\mathrm{x}}$ and VOCs.

Many different types of VOCs are emitted into the atmosphere, each reacting at different rates and having different mechanisms for their reactions. Because of this, they can differ significantly in their effects on ozone formation, or their "reactivity". Some compounds, such as CFCs, do not react in the lower atmosphere at all, and thus make no contribution to ground-level ozone formation. Others, such as methane, react and contribute to ozone formation, but react so slowly that their practical effect on ozone formation in urban atmospheres is negligible. Obviously, it does not make sense to regulate such compounds as ozone precursors. In recognition of this, the EPA has exempted certain compounds from such regulations on the basis of having "negligible" effects on ozone formation. Although the EPA has no formal policy on what constitutes "negligible" reactivity, in practice it has used the ozone formation potential of ethane as the standard in this regard is because ethane is the most reactive of the compounds that were initially exempted by the EPA. Therefore, the ozone formation potential of a compound relative to ethane is of particular interest when assessing whether it might be a likely candidate for exemption from regulation as an ozone precursor.

Many VOCs that would not be judged to have "negligible" reactivity under the current criterion might still have much lower ozone formation potential than average, and substituting emissions of highly reactive VOCs with such moderate-to-low reactivity VOCs would be expected to result in air quality improvements. Although the current EPA policies do not encourage such substitutions, it has been proposed to implement reactivity-based policies on a voluntary basis in consumer product regulations in California (CARB, 1999), and the EPA is currently re-evaluating its reactivity-based VOC policies (Dimitriades, 1999, RRWG, 1999). Mc.Bride et al (1977) showed that adopting reactivity-based VOC control policies could result in significant cost savings in ozone reduction strategies, though a number of
difficult policy and enforcement issues need to be resolved (RRWG, 1999). Although regulatory approaches that appropriately deal with differences in VOC reactivity are still evolving, it is clear that industries whose processes result in VOC emissions will need to know how those VOCs might be classified under any such system, so they can appropriately adapt to reactivity-based policies once they are implemented. This requires an ability to reliably estimated the ozone impacts of the VOCs of interest.

Aluminum rolling mills use high molecular weight alkane mixtures as lubricants, and normal rolling mill processes may result in sufficient emissions of these compounds to be of regulatory concern. However, high molecular weight alkanes, and high molecular weight normal alkanes in particular, have been estimated to have sufficiently low ozone impacts (e.g., Carter, 1994a, Carter and Venkataraman, 1995) that exempting them from regulation as VOC ozone precursors may not be inappropriate. Because of this, the Aluminum Association contracted with the College of Engineering Center for Environmental Research and Technology to provide the data and conduct the analysis needed to quantitatively assess the ozone impacts of representative components of aluminum rolling mill lubricants.

The process involved in of quantitatively assessing ozone impacts of compounds for which ozone impact data are not available involves at a minimum the following steps. (1) Environmental chamber experiments are carried out to determine the effects of the subject compounds on $\mathrm{O}_{3}$ formation and other measures of air quality under various conditions. (2) Gas-phase atmospheric chemical mechanisms for the relevant atmospheric reactions of the compounds are developed based on available laboratory data and theoretical estimates and their ability to predict of ozone impacts and other relevant measures of reactivity are evaluated by comparing model predictions with the results of the environmental chamber experiments. If necessary, uncertain portions of the mechanism are modified to yield predictions that are consistent with the chamber data. (3) The experimentally evaluated mechanisms are then incorporated into models for ozone formation in the atmosphere, and these models are then used to determine the effects of adding these compounds to existing emissions in scenarios representing various urban conditions where ozone formation is a problem. The results are then compared with the ozone formation potentials of other representative compounds, including ethane. A comparison of the ozone impacts of the subject compounds to those of ethane can be used in judging whether it is appropriate to exempt the compound from regulation as a VOC ozone precursor under the current standard used by the EPA. A comparison of their ozone impacts compared to the mixture of reactive VOCs emitted from all anthropogenic sources can be used to assess the relative ozone benefits of regulating emissions of the subject compounds compared to regulating all VOC emissions equally.

The first phase of this project consisted of conducting such experiments and analysis on the ozone impacts of the $\mathrm{C}_{12}$ to $\mathrm{C}_{16}$ normal alkanes. This phase was completed and the results are documented by Carter et al (1996). It was found that as predicted these normal alkanes had relatively low ozone impacts that are comparable to those of ethane, though the impacts varied significantly from scenario to scenario. In the second phase of the program, experiments were carried out to assess the ability of current mechanisms to predict the ozone impacts of the representative high molecular weight cycloalkanes hexyl cyclohexane and octyl cyclohexane. During the intervening period the general atmospheric chemical
mechanism used in the 1996 Phase 1 report underwent a significant update (Carter, 2000), and thus the environmental chamber mechanism evaluation and atmospheric reactivity predictions for the $\mathrm{C}_{\geq 12}$ normal alkanes as given by Carter et al (1996) are out of date. This Phase 2 report therefore updates the mechanism evaluations and reactivity calculations for the $\mathrm{C}_{12}-\mathrm{C}_{16}$ normal alkanes, as well as documenting the Phase 2 experiments, mechanism evaluations, and reactivity calculations for the representative cycloalkanes.

# EXPERIMENTAL AND DATA ANALYSIS METHODS 

## Environmental Chamber Experiments

## Overall Experimental Approach

Most of the environmental chamber experiments for this program consisted of measurements of "incremental reactivities" of the subject VOCs under various conditions. These involve two types of irradiations of model photochemical smog mixtures. The first is a "base case" experiment where a mixture of reactive organic gases (ROGs) representing those present in polluted atmospheres (the "ROG surrogate") is irradiated in the presence of oxides of nitrogen $\left(\mathrm{NO}_{\mathrm{x}}\right)$ in air. The second is the "test" experiment that consists of repeating the base case irradiation except that the VOC whose reactivity is being assessed is added. The differences between the results of these experiments provide a measure of the atmospheric impact of the test compound, and the difference relative to the amount added is a measure of its reactivity. To provide data concerning the reactivities of the test compound under varying atmospheric conditions, three types of base case experiments were carried out:

Mini-Surrogate Experiments. This base case employed a simplified ROG surrogate and relatively low ROG/ $\mathrm{NO}_{\mathrm{x}}$ ratios. Low $\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ ratios represent "maximum incremental reactivity" (MIR) conditions, which are most sensitive to VOC effects. This is useful because it provides a sensitive test for the model, and also because it is most important that the model correctly predict a VOC's reactivity under conditions where the atmosphere is most sensitive to the VOCs. The ROG mini-surrogate mixture employed consisted of ethene, $n$-hexane, and m-xylene. This surrogate was employed in our previous studies (Carter et al, 1993; 1995a-c, 1997a, 2000a), and was found to provide a more sensitive test of the mechanism than the more complex surrogates that more closely represent atmospheric conditions (Carter et al, 1995b). This high sensitivity to mechanistic differences makes the mini-surrogate experiments most useful for mechanism evaluation. The average initial reactant concentrations of these experiments were (in ppm): NO: $0.22, \mathrm{NO}_{2}: 0.09$, n-hexane: 0.5 , ethene: 0.8 , and m-xylene: 0.14
$\underline{\text { High }} \mathrm{NO}_{\underline{x}}$ Full Surrogate Experiments. This base case employed a more complex ROG surrogate under somewhat higher, though still relatively low, $\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ conditions. While less sensitive to the mechanism employed, experiments with a more representative ROG surrogate are needed to evaluate the mechanism under conditions that more closely resembling the atmosphere. The ROG surrogate employed was the same as the 8 -component "lumped molecule" surrogate as employed in our previous study (Carter et al. 1995b), and consists of n-butane, n-octane, ethene, propene, trans-2-butene, toluene, m-xylene, and formaldehyde. Calculations have indicated that use of this 8 -component mixture will give essentially the same results in incremental reactivity experiments as actual ambient mixtures (Carter et al. 1995b). The average initial reactant concentrations of these experiments were (in ppm): NO: $0.25, \mathrm{NO}_{2}: 0.10$, n-butane: 0.4 , n-octane: 0.12 , ethene: 0.08 , propene: 0.07 , trans-2-butene: 0.07 , toluene: 0.11 and mxylene: 0.10 .

Full Surrogate, low $\mathrm{NO}_{\underline{x}}$ Experiments. This base case employing the same 8-component "lumped molecule" surrogate as the full surrogate experiments described above, except that lower $\mathrm{NO}_{\mathrm{x}}$ levels (higher $\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ ratios) were employed to represent $\mathrm{NO}_{\mathrm{x}}$-limited conditions. Such experiments are necessary to assess the ability of the model to properly simulate reactivities under conditions where $\mathrm{NO}_{\mathrm{x}}$ is low. The initial ROG and $\mathrm{NO}_{\mathrm{x}}$ reactant concentrations were comparable to those employed in our previous studies (Carter et al. 1995b, 1997a, 2000a). The average initial NO and $\mathrm{NO}_{2}$ were 0.11 and 0.06 ppm, respectively, and the initial concentrations of the 8 ROG surrogate components were the same as in the high $\mathrm{NO}_{\mathrm{x}}$ full surrogate experiments.

An appropriate set of control and characterization experiments necessary for assuring data quality and characterizing the conditions of the runs for mechanism evaluation were also carried out. These are discussed where relevant in the results or modeling methods sections (see also Carter et al, 1995c, 2000a).

## Environmental Chambers

Two environmental chambers were employed in this program, which differed primarily in the type of light source employed. Most experiments were carried out using the CE-CERT "Dividable Teflon Chamber" (DTC) with a blacklight light source. This consists of two $\sim 6000$-liter 2-mil heat-sealed FEP Teflon reaction bags located adjacent to each other and fitted inside an $8^{\prime} \times 8^{\prime} \times 8^{\prime}$ framework, and which uses two diametrically opposed banks of 32 Sylvania $40-\mathrm{W}$ BL black lights as the light source. The lighting system in the DTC was found to provide so much intensity that only half the lights were used for irradiation. The air conditioner for the chamber room was turned on before and during the experiments. Four air blowers that are located in the bottom of the chamber were used to help cool the chamber as well as mix the contents of the chamber. The CE-CERT DTC is very similar to the SAPRC DTC which is described in detail elsewhere (Carter et al, 1995b,c).

The blacklight light source has the advantage of being relatively inexpensive to operate and provides a reasonably good simulation of natural sunlight in the region of the spectrum that is important in affecting most photolysis reactions of importance for non-aromatic VOCs (Carter et al, 1995c,d). This is therefore probably appropriate for studies of reactivities of compounds, such as alkanes, which are not photoreactive or believed to form significant yields of photoreactive products whose action spectra are not well characterized. However, to verify that this is the case, it is useful to carry out at least some experiments using a light source such as xenon arcs, which give a better simulation of sunlight throughout the full spectral range. Therefore, the CE-CERT xenon arc Teflon Chamber (CTC) was used for some of the experiments carried out for this project.

The CE-CERT CTC consists of two $\sim 3500$-liter 4 ' x $4{ }^{\prime}$ x $8^{\prime}$ FEP Teflon reaction bags located adjacent to each other at one end of an $8^{\prime} \times 12$ room with reflective aluminum paneling on all surfaces. Four 6.5 KW xenon arc lights were mounted on the wall opposite the reaction bags, all in a room with walls and ceiling covered with reflective aluminum paneling to maximize light intensity and homogeneity. As discussed elsewhere (Carter et al. 1995d), this light source gives the closest approximation available of the ground-level solar spectrum for an indoor chamber. The room with the
chamber has a sufficiently powerful air conditioning system to remove the heat input caused by the lights to maintain an approximately constant ambient temperature of $\sim 25^{\circ} \mathrm{C}$. A movable panel is used to block the lights when they are first turned on and warming up, which is raised to begin the irradiation. The chamber was very similar to the Statewide Air Pollution Research Center's Xenon arc Teflon Chamber (SAPRC XTC) which is described in detail elsewhere (Carter et al. 1995c,d).

Both the DTC and CTC are designed to allow simultaneous irradiations of experiments with and without added test reactants under the same reaction conditions. Since the chambers are actually two adjacent FEP Teflon reaction bags, two mixtures can be simultaneously irradiated using the same light source and with the same temperature control system. These two reaction bags are referred to as the two "sides" of the chambers (Side A and Side B) in the subsequent discussion. The sides are interconnected with two ports, each with a box fan, which rapidly exchange their contents to assure that base case reactants have equal concentrations in both sides. In addition, a fan is located in each of the reaction bags to rapidly mix the reactants within each chamber. The ports connecting the two reactors can then be closed to allow separate injections on each side, and separate monitoring of each side.

## Experimental Procedures

The reaction bags were flushed with dry air produced by an AADCO air purification system for 14 hours ( $6 \mathrm{pm}-8 \mathrm{am}$ ) on the nights before experiments. The continuous monitors were connected prior to reactant injection and the data system began logging data from the continuous monitoring systems. The reactants were injected as described below (see also Carter et al, 1993, 1995c). The common reactants were injected in both sides simultaneously using a three-way (one inlet and two outlets connected to side A and B respectively) bulb of 2 liters in the injection line and were well mixed before the chamber was divided. The contents of each side were blown into the other using two box fans located between them. Mixing fans were used to mix the reactants in the chamber during the injection period, but these were turned off prior to the irradiation. The sides were then separated by closing the ports that connected them, after turning all the fans off to allow their pressures to equalize. After that, reactants for specific sides (the test compound in the case of reactivity experiments) were injected and mixed. In case of CTC chamber the lights are turned on after lowering a metal baffle between the lights and the reactors, and the lights are allowed to warm up for at least 30 minutes. Irradiation in the chamber is begun by raising the baffle between the lights and the reactors, and the irradiation proceeds for 6 hours. After the run, the contents of the chamber were emptied by allowing the bags to collapse, and then the chamber was flushed with purified air. The contents of the reactors were vented into a fume hood.

The procedures for injecting the various types of reactants were as follows. The NO and $\mathrm{NO}_{2}$ were prepared for injection using a high vacuum rack. Known pressures of NO, measured with MKS Baratron capacitance manometers, were expanded into Pyrex bulbs with known volumes, which were then filled with nitrogen (for NO ) or oxygen (for $\mathrm{NO}_{2}$ ). The contents of the bulbs were then flushed into the chamber with nitrogen. The gaseous reactants were prepared for injection either using a high vacuum rack or a gas-tight syringes whose amounts were calculated to achieve the desired concentrations in the
chamber. Sufficiently volatile liquid reactants (which included all the liquid surrogate components used in this study) were injected using a micro syringe into a 1 -liter Pyrex bulb equipped with stopcocks on each end and a port for the injection of the liquid. Then one end of the bulb was attached to the injection port of the chamber and the other to a nitrogen source. The stopcocks were then opened, and the contents of the bulb were flushed into the chamber with a combination of nitrogen and heat gun for approximately 5 minutes. The high molecular weight cycloalkanes were injected by introducing the desired amount of liquid measured with a microsyringe into a tube wrapped with heat tape, then flushing the contents of the tube into the chamber with Aadco air at about 2 liters/minute for 10-20 minutes, with the tube was heated to $\sim 250 \mathrm{~K}$.

Formaldehyde was prepared in a vacuum rack system by heating paraformaldehyde in an evacuated bulb until the pressure corresponded to the desired amount of formaldehyde. The bulb was then closed and detached from the vacuum system and its contents were flushed into the chamber with dry air through the injection port.

## Kinetic Experiments

In addition to the environmental chamber experiments for mechanism evaluation, a limited number of experiments were carried out to determine the rate constant for the reactions of OH radicals with hexyl cyclohexane and octyl cyclohexane, using a relative rate technique. Experiments were carried out using either a $\sim 3200$-liter blacklight-irradiated chamber constructed of 2 mil FEP Teflon film that was used in our previously reported kinetic experiments (Carter et al, 2000a), or Side A of the DTC chamber described above. The light intensity in the $\sim 3200$ liter chamber was approximately twice that of the lights used in the DTC. Pure dry air from an AADCO air purification system was used for all experiments, and the experiments were carried out at ambient temperature (approximately $295-298^{\circ} \mathrm{K}$ ).

OH Radicals were generated by the photolysis of methyl nitrite in the presence of NO. The methyl nitrate was synthesized at Roger Atkinson's laboratory at the Air Pollution Research Center as described previously (Atkinson et al, 1981), and was transferred to our laboratory in the gas phase using $\sim 0.6$ liter Pyrex bulb covered with the black tape. The methyl nitrite was prepared for injection using a high vacuum rack as described above. The contents of the bulb were then flushed into the chamber with the Aadco air after all the reactants were already injected. Approximately 2 ppm of methyl nitrite, 3 ppm of NO and 0.25 ppb each of m -xylene, $\mathrm{n}-\mathrm{C}_{12}, \mathrm{n}-\mathrm{C}_{14}$, hexyl cyclohexane, and octyl cyclohexane were injected into the reactor in the dark. After the reactants were injected and mixed, the concentrations of the VOC reactants were monitored by gas chromatography until reproducible concentrations were measured. The analysis methods employed were the same as employed in the reactivity experiments for the hexyl and octyl cyclohexanes, as described below, and all the VOCs were analyzed simultaneously using the same instrument. Then the lights were turned on for brief periods ( $5-10$ minutes, with the time increasing as the experiment progressed) and then turned off. The reactant concentrations were measured between each irradiation.

The experiments employed m-xylene as the reference compound, hexyl cyclohexane and octyl cyclohexane as the compounds whose OH rate constants were to be determined and n -dodecane and n -tetradecane for verification purposes.

## Analytical Methods

Ozone and nitrogen oxides $\left(\mathrm{NO}_{\mathrm{x}}\right)$ were continuously monitored using commercially available continuous analyzers with Teflon sample lines inserted directly into the chambers. The sampling lines from each side of the chamber were connected to solenoids that switched from side to side every 10 minutes, so the instruments alternately collected data from each side. Ozone was monitored using a Dasibi 1003-AH UV photometric ozone analyzer and NO and total oxides of nitrogen (including organic nitrates and perhaps $\mathrm{HNO}_{3}$ ) were monitored using a Teco Model 42 chemiluminescent $\mathrm{NO} / \mathrm{NO}_{\mathrm{x}}$ monitor. The output of these instruments, along with that from the temperature sensors and the formaldehyde instrument, were attached to a computer data acquisition system, which recorded the data at 10 minutes intervals for ozone, NOx and temperature (and at 15 minutes for formaldehyde), using 30 second averaging times. This yielded a sampling interval of 20 minutes for taking data from each side.

The Teco instrument and Dasibi CO analyzer were calibrated prior to each experiment using a certified NO and CO source and CSI 1700 gas-phase titration calibrator. The Dasibi ozone analyzer was calibrated against transfer standard ozone analyzer using transfer standard method in an interval of three months and was check with CSI ozone generator for each experiment to assure that the instrument worked properly. The details were discussed elsewhere (Carter et al, 1995c)

Organic reactants other than formaldehyde were measured by gas chromatography with FID detection as described elsewhere (Carter et al. 1993; 1995c). GC samples were taken for analysis at intervals from 20 minutes to 30 minutes either using 100 ml gas-tight glass syringes or by collecting the 100 ml sample from the chamber onto Tenax-GC solid adsorbent cartridge. These samples were taken from ports directly connected to the chamber after injection and before irradiation and at regular intervals after irradiation was started. The sampling method employed for injecting the sample onto the GC column depended on the volatility or "stickiness" of the compound. For analysis of the more volatile species, which includes all the base ROG surrogate compounds monitored in this study, the contents of the syringe were flushed through a 10 ml and 5 ml stainless steel or $1 / 8^{\prime}$ Teflon tube loop and subsequently injected onto the column by turning a gas sample valve. For analysis of the hexyl and octyl cyclohexanes, and also m -xylene, $\mathrm{n}-\mathrm{C}_{12}$ and $\mathrm{n}-\mathrm{C}_{14}$ during the kinetic experiments, the samples were collected using a Tenax-GC cartridge. The cartridge was then placed in series with the GC column, where it was heated to $300^{\circ} \mathrm{C}$ to desorb the sample, which was then cryofocused on the column.

The calibrations for the GC analyses for most compounds were carried out by sampling from chambers or vessels of known volume into which known amounts of the reactants were injected, as described previously (Carter et al, 1995c).

Formaldehyde was monitored using an adaptation of the diffusion scrubber method developed by Dasgupta et al (1988, 1990), as described by Carter et al (1995c). It was calibrated using a formaldehyde diffusion tube whose weight loss was monitored over time. The system cycled between zero, calibrate, and sample modes to correct for zero and span drifts.

## Characterization Methods

## Temperature

Three temperature thermocouples were used to monitor the chamber temperature, two of which were located in the sampling line of continuous analyzers to monitor the temperature in each side. The third one was located in the outlet of the air conditioning system used to control the chamber temperature. The temperature range in these experiments was typically 25-30 C.

## Xenon Arc Light Source

The spectrum of the xenon arc light source was measured several (usually five) times during each CTC experiment using a LiCor LI-1800 spectroradiometer. The absolute light intensity in this chamber was measured by "photostationary state" $\mathrm{NO}_{2}$ actinometry experiments and by $\mathrm{Cl}_{2}$ actinometry, which were primarily carried out prior to the period of the experiments discussed in this report (Carter et al, 1997a). The photostationary state experiments consisted of simultaneous measurements of photostationary state concentrations of $\mathrm{NO}, \mathrm{NO}_{2}$, and $\mathrm{O}_{3}$ in otherwise pure air, with the $\mathrm{NO}_{2}$ photolysis rate being calculated from the $[\mathrm{NO}]\left[\mathrm{O}_{3}\right] /\left[\mathrm{NO}_{2}\right]$ ratio (Carter et al. 1997a). The $\mathrm{Cl}_{2}$ actinometry experiments consisted of photolyzing $\sim 0.1 \mathrm{ppm}$ of $\mathrm{Cl}_{2}$ in $\sim 1 \mathrm{ppm}$ of n-butane, calculating the $\mathrm{Cl}_{2}$ photolysis rate from the rate of consumption of n-butane, and then calculating the corresponding $\mathrm{NO}_{2}$ photolysis rate from the absorption cross sections and quantum yields for $\mathrm{NO}_{2}$ and $\mathrm{Cl}_{2}$ (assuming unit quantum yields for $\mathrm{Cl}_{2}$ ) and the spectral distribution of the light source (Carter et al, 1997a).

Relative trends in light intensity with time are obtained using the quartz tube method of Zafonte et al. (1977), modified as discussed by Carter et al. ( $1995 \mathrm{c} ; 1997 \mathrm{a}$ ). The results of these experiments were analyzed to determine the $\mathrm{NO}_{2}$ photolysis rates for modeling as discussed by Carter et al (2000a). The $\mathrm{NO}_{2}$ photolysis rate used for modeling these experiments was $0.178 \mathrm{~min}^{-1}$ for the first CTC run in the series (CTC167), and declined to $0.141 \mathrm{~min}^{-1}$ for the last such run in the series (CTC240).

## Blacklight Light Source

The light intensity in the DTC chamber was monitored by periodic $\mathrm{NO}_{2}$ actinometry experiments utilizing the quartz tube method of Zafonte et al (1977), with the data analysis method modified as discussed by Carter et al. (1995c). The results of these experiments were tracked over time, and there was a gradual decrease in light intensity over time during most of the operational lifetime of this chamber. The actinometry results around the time of these experiments were fit reasonably well by a straight line, which
was used to determine the $\mathrm{NO}_{2}$ photolysis rates used for modeling. These were $0.211 \mathrm{~min}^{-1}$ for the first DTC run for this project (DTC315) and $0.209 \mathrm{~min}^{-1}$ for the last such run (DTC325).

The spectrum of the blacklight light source is periodically measured using a LiCor LI-1200 spectroradiometer, and found to be essentially the same as the general blacklight spectrum recommended by Carter et al (1995c) for use in modeling blacklight chamber experiments

## Dilution

The dilution of the chambers due to sampling is expected to be small because the flexible reaction bags can collapse as samples are withdrawn for analysis. Also, the chambers were designed to operate under slightly positive pressure, so any small leaks would result in reducing the bag volume rather than diluting the contents of the chamber. Information concerning dilution in an experiment can be obtained from relative rates of decay of added VOCs that react with OH radicals with differing rate constants (Carter et al. 1993; 1995c). Most experiments had a more reactive compound such as m-xylene and n-octane present either as a reactant or added in trace amounts to monitor OH radical levels. Trace amounts ( $\sim 0.1 \mathrm{ppm}$ ) of n -butane were also added to experiments if needed to provide a less reactive compound for monitoring dilution. In addition, specific dilution check experiments such as CO irradiations were carried out. Based on these results, the dilution rate was found to be negligible in this chamber in most experiments, generally being less than $0.3 \%$ per hour.

## Reactivity Data Analysis Methods

As indicated above, most of the experiments for this program consisted of simultaneous irradiation of a "base case" reactive organic gas (ROG) surrogate - $\mathrm{NO}_{x}$ mixture in one of the dual reaction chambers, together with an irradiation, in the other reactor, of the same mixture with added. The results are analyzed to yield two measures of VOC reactivity: the effect of the added VOC on the amount of NO reacted plus the amount of ozone formed, and integrated OH radical levels. These are discussed in more detail below.

The first measure of reactivity is the effect of the VOC on the change in the quantity $\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]$, or $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$. As discussed elsewhere (e.g., Johnson, 1983; Carter and Atkinson, 1987; Carter and Lurmann, 1990, 1991, Carter et al, 1993, 1995a), this gives a direct measure of the amount of conversion of NO to $\mathrm{NO}_{2}$ by peroxy radicals formed in the photooxidation reactions, which is the process that is directly responsible for ozone formation in the atmosphere. (Johnson calls it "smog produced" or "SP".) The incremental reactivity of the VOC relative to this quantity, which is calculated for each hour of the experiment, is given by

$$
\begin{equation*}
\operatorname{IR}\left[\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)_{\mathrm{t}}^{\mathrm{VOC}}\right]=\frac{\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)_{\mathrm{t}}^{\mathrm{Test}}-\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)_{\mathrm{t}}^{\text {Base }}}{[\mathrm{VOC}]_{0}} \tag{I}
\end{equation*}
$$

where $\Delta([\mathrm{O} 3]-[\mathrm{NO}])_{\mathrm{t}}{ }^{\text {Test }}$ is the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ measured at time t from the experiment where the test VOC was added, $\Delta\left([\mathrm{O} 3]-[\mathrm{NO})_{\mathrm{t}}{ }^{\text {Base }}\right.$ is the corresponding value from the corresponding base case run, and $[\mathrm{VOC}]_{0}$ is the amount of test VOC added. An estimated uncertainty for $\operatorname{IR}\left[\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)\right]$ is derived based on assuming an $\sim 3 \%$ uncertainty or imprecision in the measured $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ values. This is consistent with the results of the side equivalency test, where equivalent base case mixtures are irradiated on each side of the chamber.

Note that reactivity relative to $\Delta([\mathrm{O} 3]-[\mathrm{NO}])$ is essentially the same as reactivity relative to $\mathrm{O}_{3}$ in experiments where $\mathrm{O}_{3}$ levels are high, because under such conditions $[\mathrm{NO}]_{t}^{\text {base }} .[\mathrm{NO}]_{t}^{\text {test }} .0$, so a change in $\Delta([\mathrm{O} 3]-[\mathrm{NO}])$ caused by the test compound is due to the change in $\mathrm{O}_{3}$ alone. However, $\Delta([\mathrm{O} 3]-[\mathrm{NO}])$ reactivity has the advantage that it provides a useful measure of the effect of the VOC on processes responsible for $\mathrm{O}_{3}$ formation even in experiments where $\mathrm{O}_{3}$ formation is suppressed by relatively high NO levels.

The second measure of reactivity is the effect of the VOC on integrated hydroxyl $(\mathrm{OH})$ radical concentrations in the experiment, which is abbreviated as "IntOH" in the subsequent discussion. This is an important factor affecting reactivity because radical levels affect how rapidly all VOCs present, including the base ROG components, react to form ozone. If a compound is present in the experiment that reacts primarily with OH radicals, then the IntOH at time $t$ can be estimated from

$$
\begin{equation*}
\mathrm{IntOH}_{\mathrm{t}}=\frac{\ln \left([\text { tracer }]_{0} /[\text { tracer }]_{\mathrm{t}}\right)-\mathrm{Dt}}{\mathrm{kOH}^{\text {tracer }}} \tag{II}
\end{equation*}
$$

where $[\text { tracer }]_{0}$ and $[\text { tracer }]_{\mathrm{t}}$ are the initial and time $=\mathrm{t}$ concentrations of the tracer compound, $\mathrm{kOH}^{\text {tracer }}$ its OH rate constant, and D is the dilution rate in the experiments. The latter was found to be small and was neglected in our analysis. The concentration of tracer at each hourly interval was determined by linear interpolation of the experimentally measured values. M-xylene was used as the OH tracer in these experiments because it is a surrogate component present in all experiments, its OH rate constant is known (the value used was $2.36 \times 10^{-11} \mathrm{~cm}^{3} \mathrm{molec}^{-1} \mathrm{~s}^{-1}$ [Atkinson, 1989]), and it reacts relatively rapidly.

The effect of the VOC on OH radicals can thus be measured by its IntOH incremental reactivity, which is defined as

$$
\begin{equation*}
\mathrm{IR}[\operatorname{IntOH}]_{\mathrm{t}}=\frac{\mathrm{IntOH}_{\mathrm{t}}^{\text {Test }}-\mathrm{IntOH}_{\mathrm{t}}^{\text {Base }}}{[\mathrm{VOC}]_{0}} \tag{III}
\end{equation*}
$$

where $\operatorname{IntOH}$ est and $\mathrm{IntOH}^{\text {Base }}$ are the IntOH values measured at time t in the added VOC and the base case experiment, respectively. The results are reported in units of $10^{6} \mathrm{~min}$. The uncertainties in IntOH and $\operatorname{IR}[\mathrm{IntOH}]$ are estimated based on assuming an $\sim 2 \%$ imprecision in the measurements of the m -xylene concentrations. This is consistent with the observed precision of results of replicate analyses of this compound.

## CHEMICAL MECHANISMS

## General Atmospheric Photooxidation Mechanism

The chemical mechanism used in the environmental chamber and atmospheric model simulations in this study is the "SAPRC-99" mechanism that is documented in detail by Carter (2000). This mechanism represents a complete update of the SAPRC-90 mechanism of Carter (1990) and the SAPRC-97 mechanism of Carter et al (1997a), and incorporates recent reactivity data from a wide variety of VOCs, including those discussed in this report. This includes assignments for $\sim 400$ types of VOCs, and can be used to estimate reactivities for $\sim 550$ VOC categories. A condensed version, developed for use in regional models, is used to represent base case emissions in the atmospheric reactivity simulations discussed in this report. A unique feature of this mechanism is the use of a computerized system to estimate and generate complete reaction schemes for most non-aromatic hydrocarbons and oxygenates in the presence of $\mathrm{NO}_{x}$, from which condensed mechanisms for the model can be derived. This includes the mechanisms for the higher alkanes discussed in this report and the mechanisms used for their major reactive oxygenated products. The SAPRC-99 mechanism was evaluated against the results of almost 1700 environmental chamber experiments carried out at the University of California at Riverside, including experiments to test ozone reactivity predictions for over 80 types of VOCs. This includes experiments and VOCs discussed in this report.

A listing of the mechanism as used in the model simulations in this report is given in Appendix A. This consists of the "base mechanism" representing the reactions of the inorganics and common organic products, the reactions of the specific VOCs used in the environmental chamber experiments (including the three test compounds whose mechanisms are discussed in the following sections), and the reactions of the lumped model species used when representing base case VOCs in the ambient reactivity simulations. The mechanisms used for the higher molecular alkanes are discussed in more detail below. The report of Carter (2000) can be consulted for a more detailed discussion of the other portions of the mechanism.

## Atmospheric Reactions of $\mathrm{C}_{\geq 12}$ Alkanes

Available laboratory information concerning the gas-phase atmospheric reactions of the alkanes has been reviewed by Atkinson (1997), and the most recent relevant information is discussed by Carter (2000). The only significant gas-phase atmospheric reaction of alkanes is the reaction with OH radicals. Alkanes do not absorb light in the wavelength region provided by ground-level sunlight ( $\lambda \geq 300 \mathrm{~nm}$ ) (Calvert and Pitts, 1966), and rate constants for their reactions with other reactive atmospheric species (e.g., $\mathrm{O}_{3}, \mathrm{NO}_{3}$ radicals, $\mathrm{O}\left({ }^{3} \mathrm{P}\right)$ atoms) are too low for them to be of significance (Atkinson 1997, and references therein). Therefore, we will consider only reactions of alkanes with OH radicals.

Data are available for the OH radical rate constants for all the $n$-alkanes through $n-\mathrm{C}_{16}$, for various branched alkane isomers up to $\sim \mathrm{C}_{10}$, and for various cyclic alkane up to $\mathrm{C}_{12}$. The OH radical rate constants and temperature dependence expressions that are used in the SAPRC-99 mechanism (Carter, 2000) for the higher molecular weight $\left(\mathrm{C}_{\geq 7}\right)$ alkanes for which data are available are summarized on Table 1. Most of the rate constant expressions on Table 1 are those recommended in the review by Atkinson (1997), but a few more recently measured rate constants are also given. Based on the available kinetic data, Atkinson (1987) developed a structure-estimation method that can be used to estimate OH radical rate constants for alkanes and other types of compounds. The performance of this method, as updated by Kwok and Atkinson (1995), in predicting is shown on Table 1, where it can be seen that the rate constants for most compounds are predicted to within $\pm 25 \%$. Thus, the method of Kwok and Atkinson (1995) serves as a good basis for estimating OH radical rate constants for $\mathrm{C}_{\geq 12}$ alkanes whose rate constants have not been measured. The one exception is 3,4-diethyl hexane, where steric effects may be slowing down the rate of reaction at the two tertiary hydrogens in the molecule.

The reaction of OH with alkanes occurs by the abstraction of an H atom from one of the various positions on the molecule, forming $\mathrm{H}_{2} \mathrm{O}$ and the corresponding alkyl radical. The alkyl radical can then add $\mathrm{O}_{2}$ to form the corresponding peroxy radical that, in the presence of $\mathrm{NO}_{\mathrm{x}}$, will primarily react with NO to form $\mathrm{NO}_{2}$ and the corresponding alkoxy radical or the corresponding alkyl nitrate. These are shown below in the case of the radical formed from reaction of OH at the 3-position of n -octane.

$$
\begin{gather*}
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{3}+\mathrm{OH} \rightarrow \mathrm{H}_{2} \mathrm{O}+\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\cdot) \mathrm{CH}_{2} \mathrm{CH}_{3}  \tag{1}\\
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\cdot) \mathrm{CH}_{2} \mathrm{CH}_{3}+\mathrm{O}_{2} \rightarrow \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OO} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3}  \tag{2}\\
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OO} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3}+\mathrm{NO} \rightarrow \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}\left(\mathrm{ONO}_{2}\right) \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{3}  \tag{3}\\
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OO} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3}+\mathrm{NO} \rightarrow \mathrm{NO}_{2}+\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{O} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3} \tag{4}
\end{gather*}
$$

The higher molecular weight alkoxy radical can react either with $\mathrm{O}_{2}$, by decomposition, or by 1,4-H shift isomerization via a 6-member ring transition state, e.g.,

$$
\begin{gather*}
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{O} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3}+\mathrm{O}_{2} \rightarrow \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{C}(\mathrm{O}) \mathrm{CH}_{2} \mathrm{CH}_{3}+\mathrm{HO}_{2}  \tag{5}\\
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{O} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3} \rightarrow \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CHO}+\mathrm{CH}_{3} \mathrm{CH}_{2}  \tag{6}\\
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{O} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3} \rightarrow \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OH}) \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\cdot) \mathrm{CH}_{2} \mathrm{CH}_{3} \tag{7}
\end{gather*}
$$

Based on available information concerning the reactions of alkoxy radicals formed in alkane photooxidation systems, the $1,4-\mathrm{H}$ shift isomerization reaction (e.g., Reaction 7) is expected to be the major process for those long chain alkoxy radicals where it can occur (Atkinson, 1997; Carter, 2000). The subsequent reactions of the bifunctional radical formed in Reaction (7) are expected to be:

$$
\begin{gather*}
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OH}) \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\cdot) \mathrm{CH}_{2} \mathrm{CH}_{3}+\mathrm{O}_{2} \rightarrow \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OH}) \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OO} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3}  \tag{8}\\
\left.\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OH}) \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OO} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3}+\mathrm{NO} \rightarrow \mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OH}) \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{ONO})_{2}\right) \mathrm{CH}_{2} \mathrm{CH}_{3}  \tag{9}\\
\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OH}) \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OO} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3}+\mathrm{NO} \rightarrow \mathrm{NO}_{2}+\mathrm{CH}_{3} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{OH}) \mathrm{CH}_{2} \mathrm{CH}_{2} \mathrm{CH}(\mathrm{O} \cdot) \mathrm{CH}_{2} \mathrm{CH}_{3} \tag{10}
\end{gather*}
$$

Table 1. Experimental and estimated rate constants for the reactions of OH radicals with $\mathrm{C}_{27}$ alkanes, as used in the SAPRC-99 mechanism (Carter, 2000). Experimental data are from the evaluation of Atkinson (1997) unless indicated otherwise.

\end{gather*}
$$

Thus the major products formed after the reaction of OH at the 3-position of n-octane are expected to be 6-hydroxy-3-octanone and $\mathrm{HO}_{2}$ with two NO to $\mathrm{NO}_{2}$ conversions, 3-octyl nitrate with the consumption of 1 NO , and 6-hydroxy-2-octyl nitrate with one NO to $\mathrm{NO}_{2}$ conversion and consumption of an additional NO. Analogous mechanisms and products are expected from the other higher n -alkanes. The predicted formation of these $\delta$-hydroxy carbonyl products from higher molecular weight has been confirmed by recent experimental product data (Eberhard et al, 1995; Kwok et al, 1996; Arey et al, 2000).

Analogous reactions can occur in the case of the higher molecular weight branched and cyclic alkanes if they have sufficiently long chains that the $1,4-\mathrm{H}$ shift can occur. Decompositions to form lower molecular weight oxygenated products and radicals that cause additional NO to $\mathrm{NO}_{2}$ conversions become relatively more important in the case of the branched alkanes because (1) decompositions forming tertiary radicals or ketones are more favorable than those forming primary radicals or aldehydes (Carter, 2000), and (2) branched alkanes tend to have shorter chains, and the possibility of forming radicals that cannot under go $1,4-\mathrm{H}$ shifts increases. It is also likely that $1,4-\mathrm{H}$ shift isomerizations become relatively less important in the case of the cycloalkanes because the bicyclic transition states required may have greater strain. For example, in the case of cyclohexane, the initially formed alkoxy radical is estimated to react with $\mathrm{O}_{2}$ about $70 \%$ of the time to form cyclohexanone (Reaction 17), with the remaining $30 \%$ reacting by decomposition with ring opening (Reaction 18), to ultimately give rise to polyfunctional products with additional NO to $\mathrm{NO}_{2}$ conversion and nitrate formation, e.g.,

\end{align*}
$$

As discussed by Atkinson (1997) and Carter (2000), except for nitrate yields in the reaction of NO with the initially formed peroxy radicals (discussed below) and qualitative information on bifunctional product formation, there is almost no experimental information on the branching ratios or product yields involved in these reactions. Therefore, the rate constant ratios involved have to be estimated in order to derive overall reaction mechanisms for these alkanes. Estimation methods exist for all the reactions involved (e.g., Carter and Atkinson, 1985; Atkinson, 1987; Carter, 2000) and serve as a basis for generating comprehensive detailed mechanisms for the atmospheric reactions of alkanes in the presence of $\mathrm{NO}_{\mathrm{x}}$ (Carter, 1990, 2000). The most recent version is incorporated into the SAPRC-99 mechanism generation system that is documented by Carter (2000) and that was used to derive the higher alkane photooxidation mechanisms used in this study.

The major aspects of the mechanisms that affect the overall ozone impacts of these higher alkanes are the overall nitrate yields from the reactions of NO with the higher molecular weight peroxy radicals, and the numbers of NO to $\mathrm{NO}_{2}$ conversions involved in product formation. The latter are determined by branching ratios involved in the alkoxy radical reactions that determine whether additional radicals are formed that result in multi-step mechanisms. The number of NO to $\mathrm{NO}_{2}$ conversions is probably not a major uncertainty in the case of the normal alkanes because isomerizations are expected to dominate in almost all cases, but this may be a greater uncertainty in mechanisms for branched and cyclic alkanes where competing decompositions or reactions with $\mathrm{O}_{2}$ may become relatively more important. Uncertainties in the predictions of product formation are probably not as important a factor affecting reactivity predictions of the alkanes. This is because the most likely mechanisms generally predict similar types of higher molecular weight bi- or polyfunctional oxygenates, and model calculations (at least for single day scenarios) tend to be relatively insensitive to assumptions about these product's mechanisms.

Probably the most important factor affecting predicted reactivities of the higher molecular concerns nitrate formation from the reactions of NO with the higher molecular weight peroxy radicals (e.g., Reactions $3,19,15,20$ and 24, above). This reaction, which becomes increasingly important as the size of the molecule increases (Carter and Atkinson, 1989a; Atkinson, 1997), represents both a radical and $\mathrm{NO}_{\mathrm{x}}$ sink. If sufficiently important these reactions can cause significant reductions in overall ozone formation potentials of the reacting VOCs, and even ozone inhibition. This is the major reason why high molecular weight alkanes tend to have very low ozone formation potentials, despite their relatively high OH radical rate constants and relatively large number of estimated NO to $\mathrm{NO}_{2}$ conversions (Carter and Atkinson, 1989b; Carter, 1994a, 2000). Information concerning the relative rates of this reaction compared to the competing formation of the alkoxy radical and $\mathrm{NO}_{2}$ comes from primarily from measurements of yields of the various secondary alkyl nitrates formed from the radicals formed initial the initial reactions of the n -alkanes and cyclohexane, and from a very limited number of measurements of primary or tertiary alkyl nitrate yields from branched alkanes (Carter and Atkinson, 1989b; Atkinson, 1997). Yields of substituted nitrates formed from the hydroxy-substituted radicals formed after $1,5-\mathrm{H}$ shift isomerizations (e.g., the rate constant ratio for Reactions 9 vs. 10,20 vs. 21 and 24 vs. 25 , above) are unknown and have to be estimated.

## Updates to the Alkane Photooxidation Mechanisms

The nitrate yields used when deriving mechanisms for the higher alkanes in the SAPRC-90 (Carter, 2000) through SAPRC-97 (Carter et. al, 1997a) mechanisms are based on the data and recommendations given by Carter and Atkinson (1989a). These are shown on Figure 1 for the secondary peroxy radicals formed from the normal alkanes. Based on these data, nitrate yields of over $30 \%$ were calculated for the radicals initially formed in the oxidation of n-octane. increasing to yields of $40-45 \%$ for the initially formed radicals from the $\mathrm{C}_{\geq 12} \mathrm{n}$-alkanes. However, the extrapolation above $\mathrm{C}_{8}$ was uncertain and was determined primarily by the nature of the curve fit parameterization used.

Mechanisms using the nitrate yield data and estimates of Carter and Atkinson (1997a) gave a good fit to the environmental chamber reactivity data for n-octane (Carter et al, 1993, 1995b, 1997a; Carter, 1995), and reasonably good fits to the data for the $\mathrm{C}_{12}-\mathrm{C}_{16} \mathrm{n}$-alkanes obtained in our Phase 1 study for this project (Carter et al, 1996). However, to obtain these fits it had to be assumed that nitrate formation from the reaction of NO from the hydroxy substituted peroxy radicals formed after the $1,4-\mathrm{H}$ shift isomerization was negligible (e.g., in Reaction 8, above). Otherwise, the predicted total nitrate yields in the overall reaction are increased by a factor of 1.5 or more, and the model predicts much greater inhibitions of radical levels and NO oxidation rates than were consistent with the environmental chamber data. This was a concern because it is not chemically reasonable for the addition of one OH on peroxy

Figure 1. Plots of experimental nitrate yields for reactions of NO with the initially formed secondary peroxy radicals formed from the normal alkanes, and the estimates incorporated in the SAPRC-90 and SAPRC-99 mechanisms derived from these data.
radicals four carbons away from the peroxy center with 8 or more carbons to reduce the nitrate yields from $30 \%$ or more to negligible levels. However, there did no appear to be any other way to reconcile the existing nitrate yield and environmental chamber data into a consistent mechanism for $n$-alkanes. This assumption was therefore incorporated in the $n$-alkane mechanism used in our report on the atmospheric ozone impacts of the $\mathrm{C}_{\geq 12} \mathrm{n}$-alkanes that was prepared previously (Carter et al, 1996).

The apparent inconsistency between environmental chamber and nitrate yield data was not the only problem associated with the previous mechanisms for the atmospheric reactions of the higher alkanes. Because the limited data indicated lower alkyl nitrate yields from the reactions of NO with primary and tertiary peroxy radicals, the SAPRC-97 and earlier mechanisms predicted that $\mathrm{C}_{\geq 8}$ branched and cyclic alkanes tended to have considerably higher ozone reactivities than the normal alkanes with the same carbon numbers. There was limited data available to test this until environmental chamber experiments were carried out using various mineral spirits mixtures, which consist primarily of complex mixtures of $\mathrm{C}_{\geq 10}$ alkanes, of which over $75 \%$ were branched or cyclic (Carter et al, 1997b). The ozone impacts of these mixtures in the environmental chamber reactivity experiments were very similar to those of $n$-alkanes in the same carbon number range, and were significantly less than predicted by mechanisms based on their branched and cyclic alkane contents (Carter et al, 1997b). This suggested that the nitrate yields in the reactions of OH radicals with these higher branched and cyclic alkanes may be closer to those for n -alkanes than was being assumed in the mechanism.

Most of the data concerning the effects of nitrate yields on carbon number come from the measurements of Atkinson et al $(1982,1984)$, and the temperature and pressure effects data come from Atkinson et al (1983b). More recently, using improved chromatographic methods, Arey et al (2000) remeasured the nitrate yields from the $\mathrm{C}_{3}-\mathrm{C}_{8} \mathrm{n}$-alkanes. They obtained significantly lower nitrate yields for the $\mathrm{C}_{\geq 5}$ radicals. In addition, Atkinson and co-workers (unpublished results, 1999) also obtained lower nitrate yields from n-decane than estimated using the parameterization of Carter and Atkinson (1989a). These new data [and old data of Atkinson et al $(1982,1984)$ corrected the revised calibration factors as indicated by the results of Arey et al (2000)] are shown on Figure 1, where they can be compared with the previous data and estimates. The revised estimates of these secondary nitrate yields as a function of carbon number, derived by Carter (2000) based on reoptimizing the parameters of Carter and Atkinson (1989a) to fit the new data, are also shown on the figure. It can be seen that the predicted nitrate yields for the $\mathrm{C}_{\geq 12}$ peroxy radicals are about $40 \%$ lower than predicted by the parameterization derived from the older data. In addition, the new data on the nitrate yield for $n$-decane tended to support the predictions that the rate of increase of the nitrate yields with the size of the molecule will fall off with carbon numbers above 8 .

As a result of these reduced nitrate yields from the initially formed peroxy radicals, it is now possible for mechanisms to successfully simulate the environmental chamber data without having to make chemically unreasonable assumptions about no nitrate formation from the reactions of NO with $\mathrm{OH}-$ substituted peroxy radicals. Only a slight reduction caused by OH substitution is assumed, based on assumed overall nitrate yields that give best fits to the chamber data for a variety of OH -substituted
organic compounds (Carter, 2000). Thus it is now possible for model predictions to simulate reactivity data for n -alkanes using a mechanism that is chemically reasonable and consistent with nitrate yield estimates used for other compounds. Thus, the SAPRC-99 mechanism estimation methods incorporate nitrate yield estimates based on these new data (Carter, 2000).

This revision in the nitrate yield estimates for secondary peroxy radicals did not totally resolve the problems indicated by the model simulations of the experiments with the mineral spirits mixtures with the branched and cyclic $\mathrm{C}_{\geq 10}$ alkanes. As indicated above, the results of these experiments indicated that the $\mathrm{C}_{\geq 10}$ branched and cyclic alkanes are much closer in reactivity to the normal alkanes than previously estimated. Two approaches were used to when deriving the revised nitrate yield estimation methods for the SAPRC-99 mechanism to reduce the differences between the model predictions of reactivities of branched and cyclic alkanes vs. normal alkanes. These are as follows:

Revised Nitrate Yield Corrections for Primary and Tertiary Radicals. The limited product data indicated that nitrate yields from primary and tertiary peroxy radicals are lower than those from the secondary peroxy radicals. In the previous mechanism, estimates for nitrate yields for these radicals were made by applying a correction factor of 0.4 for primary radicals and 0.3 for tertiary radicals, regardless of the size of the radical. Instead of using this approach, in the SAPRC-99 mechanism, the estimates for these radicals are made by reducing the effective carbon number by 1.5 when calculating the nitrate yields using the parameterization derived to fit the data for the secondary radicals (Carter, 2000). This gives about the same predicted nitrate yields for the lower molecular weight primary and tertiary radicals for which there are data (Carter and Atkinson, 1989a), but predicts that the differences between the secondary and primary or tertiary radicals decrease with size of the molecule. This is because of the leveling off of the rate of increase in the nitrate yield as the size of the molecule increases, as shown on Figure 1.

Revised Representation of Unspeciated Branched and Cyclic Alkanes in Complex Hydrocarbon Mixtures. Most of the branched and cyclic alkane constituents of mineral spirits and similar higher molecular weight petroleum-derived substances consist of highly complex mixtures of many isomers whose exact structures are unknown. In order to model the reactivities of such substances, a few representative compounds are chosen to be representative of all the branched or all the cyclic alkanes of with the same molecular weights. In the previous mechanism the compounds chosen as representative were relatively highly branched and only a single compound was used. However, GC-MS analyses of mineral spirits samples indicated that less branched compounds, whose mechanisms would be closer to those of normal alkanes, tend to be relatively more important (O'Donnell, Safety-Kleen Corp., private communication, 1997). For the updated mechanism, the unspeciated branched and cyclic alkanes on complex mixtures are represented using three compounds for each carbon number rather than a single one, and the compounds used are generally less highly branched (Carter, 2000). For example, the branched $\mathrm{C}_{12}$ alkanes, which previously were represented by 3,6-diethyl octane, are now represented by $50 \%$ 3,6-dimethyl decane, $25 \% 5$-methyl undecane and $25 \%$ 3-methyl undecane. The cyclic $\mathrm{C}_{12}$ alkanes, which were previously represented by 1,3,5-diethylcyclohexane are now represented by $35 \%$ hexyl cyclohexane and $33 \%$ each 1,3,5 diethyl cyclohexane and 1-methyl 4-pentyl cyclohexane. This should
tend to reduce differences in reactivities between normal alkanes and branched and cyclic alkanes with the same carbon number.

## Representation of $\mathrm{C}_{12}-\mathrm{C}_{16}$ Normal and Cyclic Alkanes in the SAPRC-99 Mechanism

The detailed mechanisms for the atmospheric reactions of the higher alkanes in the presence of $\mathrm{NO}_{\mathrm{x}}$ were derived using the SAPRC-99 mechanism generation and estimation system based on the considerations discussed in the previous sections. These then were used to derive the condensed representation of these products in terms of SAPRC-99 model species, as shown in Table A-2 in Appendix A for the specific branched and cyclic compounds that were represented in the model simulations in this report. The OH radical rate constants used for the normal alkanes were the experimental values as shown on Table 1, above. For hexyl cyclohexane the rate constant used was that derived in this study as shown on Table 1. For octyl cyclohexane it was judged that experimental measurement was sufficiently uncertain that the estimate derived using the structure-reactivity methods of Kwok and Atkinson is more likely to be reliable, so the estimated rate constant was used. These data for the alkyl cyclohexanes are discussed n the Results section, below.

Table 2 gives a summary of the yields of the SAPRC-99 product or radical operator model species that were derived for the $\mathrm{C}_{\geq 12}$ normal and branched alkanes that were studied in this project. Here, RO2-R. represents the formation of peroxy radicals that ultimately react to convert NO to $\mathrm{NO}_{2}$ and form $\mathrm{HO}_{2}, \mathrm{RO} 2-\mathrm{N}$. represents the formation of peroxy radicals that ultimately react with NO to form alkyl nitrates, R 2 O 2 . represents extra NO to $\mathrm{NO}_{2}$ conversions formed by peroxy radicals formed in multi-step mechanisms, RCHO represents higher aldehyde products, and PROD2 represents reactive ketones and non-aldehyde bifunctional products that are predicted to be formed.

Table 2. Summary of radical operator and product yields used when representing the $\mathrm{C}_{\geq 12}$ normal and branched alkanes in the SAPRC-99 mechanism

| Compound | Radical Operator or Product Yields |  |  |  |  |
| :--- | :---: | :---: | :---: | :---: | :---: |
|  | RO2-R. | RO2-N. | R2O2. | RCHO | PROD2 [b] |
| n-Dodecane | 0.54 | 0.46 | 0.77 | 0.01 | 0.53 |
| n-Tetradecane | 0.53 | 0.47 | 0.76 | 0.01 | 0.52 |
| n-Pentadecane | 0.53 | 0.47 | 0.76 | 0.01 | 0.52 |
| n-Hexadecane | 0.52 | 0.48 | 0.76 | 0.01 | 0.52 |
| Hexyl Cyclohexane | 0.53 | 0.47 | 0.85 | 0.09 | 0.46 |
| Octyl Cyclohexane | 0.51 | 0.49 | 0.85 | 0.06 | 0.46 |

[a] Represented by separate model species with parameters derived based on the set of products they represent, as discussed in the text.

Note that $\mathrm{C}_{12}-\mathrm{C}_{16}$ normal alkanes have very similar representations in the SAPRC-99 mechanism, with the only difference being that the overall nitrate yields slowly increase with the size of the molecule. The alkyl cyclohexanes are predicted have very similar overall nitrate yields to the normal alkanes in the same molecular weight, but somewhat more NO to $\mathrm{NO}_{2}$ conversions caused by peroxy radicals formed in multi-step mechanisms. The slightly higher overall nitrate yields from the alkyl cyclohexanes may seem surprising in that their reactions are predicted to involve formation of tertiary peroxy radicals that are estimated to have lower nitrate yields. However, this is countered by the fact that their overall reactions involve tend to involve more steps, and therefore more peroxy radical formation, than the reactions of the corresponding $n$-alkanes (compare Reactions 1-12, above, with Reactions 12 27). This is the reason that the cycloalkanes have more NO to $\mathrm{NO}_{2}$ conversions in the overall mechanisms, as indicated by the higher R2O2. yields.

As indicated on Table 2, these normal alkanes and alkyl cyclohexanes are predicted to form significant yields of bifunctional ketone products that are normally represented by the PROD2 model species. However, for more accurate representation of the contributions of these products for use when calculating the reactivities of the individual compounds, they can also be represented using compoundproduct model species whose rate constants and parameters are adjusted based on the specific mixture of products they represent. As discussed by Carter (2000), the SAPRC-99 mechanism generation system is used to derive estimated mechanisms for these product species, and these are then used to derive he parameters in the lumped product-specific species used to represent them. This approach was employed when representing these normal and cyclic $\mathrm{C}_{\geq 12}$ alkanes in the model simulations of the chamber experiments and atmospheric reactivity calculations used in this work.

Table 3 shows the mixture of the higher ketone products that are predicted to be formed in the photooxidations of $n$-dodecane and hexyl cyclohexane. These serve as the basis for deriving the mechanisms shown for the lumped "PRD" model species for these compounds shown, which are shown on Table A-2 in Appendix A. Note that for n-dodecane the products are all just the various $\delta$-hydroxy ketones resulting from reaction at the different positions in the molecule, while a somewhat more varied mixture is predicted to be formed from hexyl cyclohexane. The product mixtures for the higher molecular weight normal and cycloalkanes discussed in this work are similar.

Table 3. Mixtures of higher ketone products predicted to be formed in the reactions of $n$-dodecane and hexyl cyclohexane with OH radicals in the presence of $\mathrm{NO}_{x}$.

## EXPERIMENTAL RESULTS

## Relative Rate Constant Measurements

The rate constants for the reactions of OH radicals with hexyl cyclohexane and octyl cyclohexane and (for control purposes) n -dodecane and n -tetradecane were measured using a relative rate method, with m -xylene used as the reference compound. The relative rate method employed has been used extensively in other laboratories for many years [see references cited by Atkinson (1989), e.g., Atkinson et al, 1981)], and involves measurements of the consumption of the various compounds in the presence of OH radicals. In this work, the OH radicals were generated either by the photolysis of methyl nitrite
(overall: $\quad \mathrm{CH}_{3} \mathrm{ONO}+\mathrm{h} v+\mathrm{O}_{2} \rightarrow \mathrm{HCHO}+\mathrm{NO}_{2}+\mathrm{OH}$ )
Excess NO is added to avoid the formation of $\mathrm{O}_{3}$ and $\mathrm{NO}_{3}$ radicals.
Assuming that the organics react only with OH radicals, the kinetic differential equations for the organics can be solved and rearranged to yield

$$
\begin{equation*}
\ln \left(\frac{[\text { Organic }]_{\mathrm{t} 0}}{[\text { Organic }]_{\mathrm{t}}}\right)-\mathrm{D}_{\mathrm{t}}=\frac{\mathrm{k}_{\text {Organic }}}{\mathrm{k}_{\text {Reference }}} \ln \left[\left(\frac{[\text { Reference }]_{\mathrm{t} 0}}{[\text { Reference }]_{\mathrm{t}}}\right)-\mathrm{D}_{\mathrm{t}}\right] \tag{IV}
\end{equation*}
$$

where $[\text { Organic }]_{t 0}$ and $[\text { Organic }]_{t}$, Reference $]_{t}$, and $[\text { Reference }]_{t}$ are the initial and time $=t$ concentrations of the test and reference compounds, respectively, $\mathrm{k}_{\text {organic }}$ and $\mathrm{k}_{\text {Reference }}$ are the test and reference compound's OH rate constant, and $\mathrm{D}_{\mathrm{t}}$ is a factor added to account for dilution due to reactant injections, leaks, etc, from the beginning of the experiment up to time $t$. Since no reactant injections were made during the experiments and the leaks in this chamber are believed to be negligible during the time period of the experiments, $D_{t}$ is assumed to be negligible in our analysis. Therefore plots of $\ln \left([\text { Organic }]_{t 0} /[\text { Organic }]_{t}\right)$ against $\ln \left([\text { Reference }]_{t 0} /[\text { Reference }]_{t}\right)$ should yield a straight line with intercept of approximately zero and a slope that is the ratio of rate constants. Given the known value of $\mathrm{k}_{\text {Reference }}$, then $\mathrm{k}_{\text {Organic }}$ can then be derived. In principle all of the compounds could be present in the same experiment but because of GC interferences and other factors generally only 2-4 test compounds are present in any given experiment.

To verify the method as employed in this study, relative rate constants were also determined for n -dodecane and n -tetradecane. These were used because their rate constants have already been measured, their physical characteristics and volatilities are similar to the test compounds of interest, and the same analytical methods are employed. Thus if there are analytical or wall loss problems associated with
conducting the experiments with the test compounds, they should also show up and yield incorrect results for these control compounds as well.

Two kinetic experiments were carried out for this project, and their conditions and detailed measurement data are given on Table 4. Plots of Equation (IV) are shown on Figure 2 for each of the four test compounds. Note that the initial reactant concentrations used when deriving these plots were determined using a least squares optimization method to minimize least squares errors in fits of the data to Equation (IV), with the initial reactant concentrations as well as the ratios of rate constants being simultaneously optimized during this process. This procedure minimizes biases introduced by experimental uncertainties in the initial reactant measurements, and allows all of the measurements to be weighted equally when determining rate constant ratios according to Equation (IV). The results are summarized on Table 5.

[a] More consistent results are obtained if these points are assumed to be anomalous and are not used in the data analysis. See text.

Figure 2. Plots of Equation (IV) for n-dodecane, n-tetradecane, hexyl cyclohexane, and octyl cyclohexane, with m-xylene as the test compound.

Figure 2 shows that good precision was obtained in the measurements of the relative rate constants for n -dodecane and hexyl cyclohexane, and fair precision in the measurements for the relative rate constants for the other two compounds if the initial data points in Run 1 are excluded. As indicated on Table 4 and shown on Figure 2, the initial measurements of $n$-dodecane and (especially) octyl cyclohexane in the first experiment appear to be anomalous, and were not used when computing the best fit to Equation (IV). The rates of decay of these compounds relative to $m$-xylene in the subsequent measurements in this experiment are consistent with the data in the second run, and the second experiment indicates no problems with the data or nonlinear plots of Equation (IV). Also, if all the data points are used the rate constant derived for octyl cyclohexane is lower than that derived for hexyl cyclohexane, which is not reasonable. However, all the data points were used when estimating the uncertainty of the rate constant ratios derived from these data, as shown on Table 4.

The rate constants determined in this work for $n$-dodecane and $n$-tetradecane are in good agreement with the literature values, suggesting that there are no systematic problems in our

Table 5. Summary of Results of OH Radical Rate Constant Measurements.

| Compound <br>  <br> $(\mathrm{m}-\mathrm{Xylene})$ <br> $[\mathrm{a}]$ | This Work [b] | Literature $\left(\mathrm{cm}^{3} \mathrm{molec}^{-1} \mathrm{~s}^{-1}\right)$ |  |  |

[a] Rate constant ratio determined to minimize least squares errors between $\ln \left([\mathrm{VOC}]_{0} /[\mathrm{VOC}]_{\mathrm{t}}\right)$ calculated using Equation (IV) and the experimentally measured values. The initial m-xylene and test VOC concentrations in each experiment were also optimized as part of this determination, to avoid biases introduced by uncertainties in initial reactant concentrations used in Equation (IV). Dilution is assumed to be negligible in all experiments. The stated error limits reflect precision on measurement only. Uncertainties for $n$-dodecane and hexyl cyclohexane based on standard deviations of least squares fits of lines to data. Uncertainties for n-tetradecane and octyl cyclohexane based on differences in rate constant ratios obtained if the initial points of the second experiment are used in the analysis.
[b] Placed on an absolute basis using kOH for m -xylene of $2.36 \times 10^{-11} \mathrm{~cm}^{3} \mathrm{molec}^{-1} \mathrm{~s}^{-1}$ at 298 K (Atkinson, 1989).
measurements. The rate constant derived for hexyl cyclohexane is in good agreement with the rate constant estimated using the methods of Kwok and Atkinson (1995), consistent with the results observed for most of the higher alkanes and the substituted cyclohexanes, as shown on Table 1. The rate constant derived for octyl cyclohexane is about $20 \%$ higher than the estimated value, which is not outside the observed for other alkanes, but not as good as expected based on the data for hexyl cyclohexane and the other substituted cyclohexanes.

Based on these data, we conclude that the rate constant for the reaction of OH radicals with hexyl cyclohexane is $1.78 \times 10^{-11} \mathrm{~cm}^{3}$ molec $^{-1} \mathrm{~s}^{-1}$, with an estimated uncertainty of around $\pm 20 \%$. Because of the problems with the initial measurements of the octyl cyclohexane in the first experiment, the rate constant measurement for the octyl cyclohexane is considered to be more uncertain than the estimate derived using the method of Kwok and Atkinson (1995). For this reason, the estimated rate constant is used in the model simulations for this compound in this work.

## Phase 2 Environmental Chamber Experiments

## Summary of Experiments and Characterization Results

Table 6 gives a chronological listing of all the experiments carried out for the second phase of this program. These consisted primarily of the experiments with the hexyl and octyl cyclohexanes, whose results are summarized in the following section. In addition, several characterization runs were carried out

Table 6. Chronological listing of the environmental chamber experiments carried out to evaluate the ozone formation potentials of hexyl cyclohexane and octyl cyclohexane.

| Run ID | Date | Title | Comments |
| :--- | :--- | :--- | :--- |
| DTC299 | $11 / 29 / 95$ | n-Butane $-\mathrm{NO}_{\mathrm{x}}$ | DTC Experiments |
| Characterization run to measure the chamber radical source. <br> Some indication of leakage on Side A, and Side A also had <br> a slightly higher NO consumption rate. NO consumption <br> rate on Side A was well fit by predictions of chamber <br> model. NO consumption rate on Side B was slightly lower <br> than predicted by chamber model, but results were within <br> the experimental variability. |  |  |  |

Table 6 (continued)

| Run ID | Date | Title | Comments |
| :---: | :---: | :---: | :---: |
| CTC162 | 2/6/96 | CO - Air Leak Test | Run conducted to measure dilution due to leakage, which was found to be negligible. |
| CTC163 | 3/13/96 | Propene - $\mathrm{NO}_{\mathrm{x}}$ | Control run for comparison with other propene runs carried out in this and other chambers. The results were within the normal range. Good side equivalency was observed. |
| CTC164 | 3/14/96 | Pure Air Irradiation | Characterization run to test for background effects. Approximately $35 \mathrm{ppb} \mathrm{O}_{3}$ formed on each side in 6 hours, somewhat more than predicted by chamber model. |
| CTC165 | 3/15/96 | Full Surrogate - $\mathrm{NO}_{\mathrm{x}}$ | Standard full surrogate - $\mathrm{NO}_{\mathrm{x}}$ mixture irradiated on both sides to test for side equivalency for this type of experiments. Good side equivalency was observed. |
| CTC166 | 3/18/96 | $\mathrm{NO}_{2}$ Actinometry | $\mathrm{NO}_{2}$ photolysis rate determined by tube method was 0.263 $\mathrm{min}^{-1}$, which yields a corrected value of $0.194 \mathrm{~min}^{-1}$ (Carter et al, 2000a). This is reasonably close to the $0.18 \mathrm{~min}^{-1}$ predicted by the overall trends in the actinometry results for this chamber (Carter et al, 2000a). |
| CTC167 | 3/19/96 | Full Surrogate + Hexyl Cyclohexane | High $\mathrm{NO}_{\mathrm{x}}$ full surrogate reactivity experiment with 0.55 ppm of hexyl cyclohexane added to Side A. Results on Table 7 and Figure 7. |
| CTC168 | 3/20/96 | Full Surrogate + Octyl Cyclohexane(B) | High $\mathrm{NO}_{x}$ full surrogate reactivity experiment with 0.47 ppm of octyl cyclohexane added to Side B. Results on Table 7 and Figure 7. |
|  | The chamber was inactive for a period and then was used for experiments for other projects |  |  |
| CTC230 | 12/12/97 | n-Butane - $\mathrm{NO}_{x}$ | Characterization run to measure the chamber radical source. The rate of NO oxidation is slightly less than the predictions of the chamber model, but the results are within the normal range. Good side equivalency observed. |
| CTC231 | 12/16/97 | Mini Surrogate + Octyl Cyclohexane | Mini-surrogate reactivity experiment with 0.25 ppm of octyl cyclohexane added to Side A. Results on Table 7 and Figure 4. |
| CTC232 | 12/17/97 | Full Surrogate + Octyl Cyclohexane | High $\mathrm{NO}_{\mathrm{x}}$ full surrogate reactivity experiment with 0.31 ppm of octyl cyclohexane added to Side B. Results on Table 7 and Figure 7. |
| CTC233 | 12/18/97 | Low $\mathrm{NO}_{\mathrm{x}}$ Full <br> Surrogate + Hexyl <br> Cyclohexane (A) | Low $\mathrm{NO}_{\mathrm{x}}$ full surrogate reactivity experiment with 0.33 ppm of hexyl cyclohexane added to Side A. Results on Table 7 and Figure 8. |
| CTC234 | 12/19/97 | Propene - $\mathrm{NO}_{\mathrm{x}}$ | Control run for comparison with other propene runs carried out in this and other chambers. The results were within the normal range. Good side equivalency was observed. |
| CTC236 | 12/23/97 | n-Butane + Chlorine Actinometry | The chlorine photolysis rate measured in this experiment corresponded to an $\mathrm{NO}_{2}$ photolysis rate of $0.148 \mathrm{~min}^{-1}$. This is in good agreement with the $\mathrm{NO}_{2}$ photolysis rate derived from the overall trends in all the actinometry experiments, which is $0.142 \mathrm{~min}^{-1}$ (Carter et al, 2000a). |

Table 6 (continued)

| Run ID | Date | Title | Comments |
| :---: | :---: | :---: | :---: |
| CTC237 | 1/6/98 | Pure air irradiation | Characterization run to test for background effects. Sides differ in ozone formation. Both sides formed $\sim 18 \mathrm{ppb}$ in 6 hours, somewhat greater than predicted by the standard chamber model. |
| CTC239 | 1/8/98 | Full Surrogate + Octyl Cyclohexane | High $\mathrm{NO}_{\mathrm{x}}$ full surrogate reactivity experiment with 0.49 ppm of octyl cyclohexane added to Side B. Results on Table 7 and Figure 7. |
| CTC240 | 1/9/98 | Low $\mathrm{NO}_{\mathrm{x}}$ Full <br> Surrogate + Octyl <br> Cyclohexane | Low $\mathrm{NO}_{\mathrm{x}}$ full surrogate reactivity experiment with 0.52 ppm of octyl cyclohexane added to Side A. Results on Table 7 and Figure 8. |
| CTC241 | 1/16/98 | n-Butane - $\mathrm{NO}_{\mathrm{x}}$ | Characterization run to measure the chamber radical source. The rate of NO oxidation agreed very well with the predictions of the standard chamber model. Good side equivalency observed. |
| CTC242 | 1/21/98 | n-Butane + Chlorine Actinometry | The chlorine photolysis rate measured in this experiment corresponded to an $\mathrm{NO}_{2}$ photolysis rate of $0.108 \mathrm{~min}^{-1}$. This is less than the $\mathrm{NO}_{2}$ photolysis rate derived from the overall trends in all the actinometry experiments, which is 0.142 $\mathrm{min}^{-1}$, but is within the scatter of the data (Carter et al, 2000a). |
| CTC244 | 9/14/98 | n-Butane - $\mathrm{NO}_{\mathrm{x}}$ | Characterization run to measure the chamber radical source. The rate of NO oxidation agreed reasonably well with the predictions of the standard chamber model. |
| CTC245 | 9/15/98 | Propene - $\mathrm{NO}_{\mathrm{x}}$ | Control run for comparison with other propene runs carried out in this and other chambers. The results were within the normal range. Good side equivalency was observed. |
| CTC247 | 9/17/98 | $\mathrm{NO}_{2}$ Actinometry | $\mathrm{NO}_{2}$ photolysis rate determined by tube method was 0.198 $\mathrm{min}^{-1}$, which yields a corrected value of $0.146 \mathrm{~min}^{-1}$ (Carter et al, 2000a). This is reasonably close to the $0.14 \mathrm{~min}^{-1}$ predicted by the overall trends in the actinometry results for this chamber (Carter et al, 2000a). |

to determine the chamber-dependent inputs needed for the model simulations of the experiments. Table 6 summarizes the purposes and relevant results from these runs. As indicated there, the results of most of these experiments were as expected based on our previous experience with these and similar chambers in our laboratories (Carter et al., 1995c and references therein; Carter et al, 2000a). Carter et al (2000a) gives a more detailed more discussion of the characterization results for these chambers during this time period, particularly with respect to light intensity and the chamber radical source. The results of these characterization experiments were taken into account when deriving the chamber dependent parameters used in the model simulations of these experiments, as discussed above and indicated on Table A-4 in Appendix A.

## Hexyl and Octyl Cyclohexane Experiments

As indicated on Table 6, six incremental reactivity experiments were carried out with hexyl cyclohexane and seven incremental reactivity experiments were carried out with octyl cyclohexane. These consisted of at least two experiments for each compound using the mini-surrogate, at least three using the higher $\mathrm{NO}_{\mathrm{x}}$ full surrogate and at least one for each compound using the low $\mathrm{NO}_{\mathrm{x}}$ full surrogate. Experiments for each compound were carried out using the blacklight-irradiated DTC and using the CTC with the xenon arc light source. The results of these experiments are summarized on Table 7. For comparison purposes, the results of the Phase 1 experiments with the $\mathrm{C}_{\geq 12}$ normal alkanes are also shown on Table 7. Concentration-time plots of selected data are given in the following section, in conjunction with the discussion of the results of the model simulations of these and the $n$-alkane experiments.

The results of these experiments indicate that the reactivity characteristics of these $\mathrm{C}_{12}$ and $\mathrm{C}_{14}$ alkyl cyclohexanes are very similar to those for the $\mathrm{C}_{12}$ and $\mathrm{C}_{14}$ normal alkanes studied previously (Carter et al, 1996). All compounds significantly inhibit OH radical levels in the experiments, and they also have significant negative effects on NO oxidation and $\mathrm{O}_{3}$ formation rates in the mini-surrogate experiments. Their effects on NO oxidation and $\mathrm{O}_{3}$ formation is much less in the full surrogate experiments, with their negative effect on $\mathrm{O}_{3}$ declining essentially to zero by the end of the irradiations. The magnitudes of the $\Delta([\mathrm{O} 3]-[\mathrm{NO}])$ and IntOH incremental reactivities are generally in the same range as observed in comparable experiments with the normal alkanes, suggesting that the amounts of inhibition caused by the reactions of these compounds are similar.

The large radical inhibiting effects in the reactions of these higher molecular weight alkanes can be attributed to the relatively high nitrate formation in the reactions of the peroxy radicals with NO, as discussed above. The NO oxidation and $\mathrm{O}_{3}$ formation rates in the mini-surrogate experiments tend to be the most sensitive to radical inhibition or initiation effects (Carter et al, 1995a), and consequently the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ reactivities are also highly negative in these experiments. On the other hand the full surrogate experiments are relatively more sensitive to the effects of the NO to $\mathrm{NO}_{2}$ conversions involved in the alkane photooxidation mechanisms, which tend to work in the opposite direction. For alkanes such as n-octane, with lower overall nitrate yields, this is sufficient to counteract the inhibiting effect of the radical inhibition involved with nitrate formation and result in positive $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ reactivities in the full surrogate experiments (Carter et al, 1995a). In the case of the $\mathrm{C}_{12}$ or higher alkanes the positive effects of the NO to $\mathrm{NO}_{2}$ conversions are not quite enough to counter the radical inhibiting effects in the full surrogate experiments, so the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ reactivities are still generally negative in most experiments.

The mechanistic implications of these results will be discussed further in the following section, in conjunction with the discussion of the model simulations of these experiments.

## MECHANISM EVALUATION

The ability of the SAPRC-99 chemical mechanism to appropriately simulate the atmospheric impacts of the higher molecular weight normal and cyclic alkanes studied was evaluated by conducting model simulations of the environmental chamber experiments carried out for both phases of this project. Although the Phase 1 study of the normal alkanes also included mechanism evaluation (Carter et al, 1996), this needed to be redone for this work because of the significant changes to the nitrate yield estimates for the higher alkanes, as discussed above. In addition, since the Phase I report of Carter et al, 1996) the overall mechanism was completely updated as discussed by Carter (2000), making the previous work out of date.

## Methods

The environmental chamber modeling methods used in this work are based on those discussed in detail by Carter and Lurmann (1990, 1991), updated as discussed by Carter et al. (1995c; 1997a, 2000a). Model simulations of environmental chamber experiments requires including in the model appropriate representations of chamber-dependent effects such as wall reactions and characteristics of the light source. The photolysis rates were derived from results of $\mathrm{NO}_{2}$ actinometry experiments and measurements of the relative spectra of the light source. In the case of the xenon arc lights used in the CTC, the spectra were derived from those measured during the individual experiments, assuming continuous linear changes in relative intensity at the various wavelengths, as discussed by Carter et al. (1997a). The thermal rate constants were calculated using the temperatures measured during the experiments, with the small variations in temperature with time during the experiment being taken into account. The computer programs and modeling methods employed are discussed in more detail elsewhere (Carter et al, 1995c). The specific values of the chamber-dependent parameters used in the model simulations of the experiments for this study are given in Table A-4 in Appendix A.

As indicated above, the chemical mechanism used in all the model simulations in this work was the SAPRC-99 mechanism documented by Carter (2000). The species, reactions, rate constants, and parameters used to calculate photolysis rates are listed in Tables A-1 through A-3 in Appendix A. Note that the mechanisms used for the higher alkanes are those derived using the SAPRC-99 mechanism generation system, as discussed in the previous sections. No adjustments were made to improve the fits of model calculations to the chamber data.

## Results

The experiments modeled are the various alkane reactivity experiments carried out in the two phases of this project, whose conditions and selected results are summarized on Table 7, above. The results of the model simulations of these experiments are shown in Figure 3 through Figure 8, which give plots of the major experimental and calculated results of these incremental reactivity experiments. These

include, for each experiment, the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ data for both the base case and the added alkane experiment, the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ incremental reactivities, calculated as the change in $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ caused by adding the alkane divided by the amount of alkane added, and the IntOH incremental reactivities, caused by the change in the IntOH measurements derived from the m-xylene consumption rates, divided by the amount of alkane added. The simulated incremental reactivities were calculated from the simulated using the same approach as the experimental incremental reactivities were calculated from the experimental data.

The results of the mini-surrogate experiments are shown on Figure 3 for the experiments with the n-alkanes, and on Figure 4 for the experiments with the hexyl cyclohexane and octyl cyclohexane. It can be seen that good fits of model simulations to the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ and IntOH reactivity data are obtained in most experiments, particularly the DTC experiments with the alkyl cyclohexanes and the IntOH reactivity simulations in almost all runs. There may be a slight tendency for the model to underpredict $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ inhibition by the n -alkanes, but the discrepancy is relatively minor. Somewhat more variable fits are obtained for n-hexadecane and octyl cyclohexane than for the $\mathrm{C}_{12}$ compounds, as might be expected given

Figure 5. Selected experimental and calculated results of the high $\mathrm{NO}_{\mathrm{x}}$ full surrogate incremental reactivity experiments with n-dodecane and n-tetradecane.

Figure 6. Selected experimental and calculated results of the high $\mathrm{NO}_{\mathrm{x}}$ full surrogate incremental reactivity experiments with n-pentadecane and n-hexadecane.
the greater uncertainties involved with handling or analyzing the higher molecular weight compounds. The difference between the fits for the DTC and CTC experiments for octyl cyclohexane is more likely due to this than to any effects of the different light source employed, since the other experiments, discussed below, indicated no significant light source differences in the mechanism performance results.

The results of the high $\mathrm{NO}_{\mathrm{x}}$ full surrogate experiments are shown on Figure 5 and Figure 6 for the n-alkanes and on Figure 7 for the cycloalkanes. Again reasonably good fits of model simulations to the data are obtained, with the model correctly predicting relatively small effects on $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ but large negative effects on IntOH. Almost as many CTC as DTC experiments were carried out for each compound, and no significant difference is observed between model simulations in the two chambers, indicating no significant light source effects. As with the mini-surrogate experiments, the ability of the model to simulate the alkyl cyclohexane experiments is comparable or even slightly better than its ability to simulate the experiments with the normal alkanes. In this case, the model performance in simulating the experiments with the $\mathrm{C}_{12}$ and the $\mathrm{C}_{16}$ alkanes is comparable.

- Test Experiment

Figure 7. Selected experimental and calculated results of the high $\mathrm{NO}_{\mathrm{x}}$ full surrogate incremental reactivity experiments with hexyl cyclohexane and octyl cyclohexane.

Figure 8. Selected experimental and calculated results of the low $\mathrm{NO}_{\mathrm{x}}$ full surrogate incremental reactivity experiments with hexyl cyclohexane and octyl cyclohexane.

The results of the limited number of low $\mathrm{NO}_{\mathrm{x}}$ full surrogate experiments carried out for this project are shown on Figure 8. Again the model performance in simulating these data is reasonably good, with the model correctly predicting the IntOH inhibition and the small effects on the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ data and the peak ozone yields. The performance of the model in simulating the octyl cyclohexane experiments is not significantly affected by the light source employed.

Overall, it can be seen that the model can simulate the results of the reactivity experiments both for the $\mathrm{C}_{\geq 12}$ normal alkanes and the $\mathrm{C}_{\geq 12}$ alkyl cyclohexanes quite well considering the difficulties in handling and analyzing these low volatility compounds. Since these include experiments with different ROG surrogates that have differing sensitivities to various aspects of the mechanism (Carter et al, 1995a) and at different $\mathrm{NO}_{\mathrm{x}}$ levels and employing different light sources, the mechanisms can be considered to be reasonably well tested. No large systematic biases were observed that indicated that adjustments to the estimated mechanism would be appropriate to improve the ability of the model to simulate these data.

## ATMOSPHERIC REACTIVITY CALCULATIONS

Incremental reactivities of VOCs have been shown to be highly dependent on environmental conditions, so reactivities measured in environmental chamber experiments cannot necessarily be assumed to be the same as those under atmospheric conditions (Carter and Atkinson, 1989b; Carter et al, 1995b). Because of this, the only method available to obtain quantitative estimates of incremental reactivities of VOCs in ambient air pollution episodes is to conduct airshed model simulations of the episodes. Since these simulations cannot be any more reliable than the chemical mechanisms used, the major objective of this program was to assess the reliability of the mechanisms for the compounds of interest for use in such calculations. As discussed above, the results of this study suggest that the SAPRC-99 alkane mechanisms serve as an appropriate basis for estimating the effects of higher molecular weight normal and cyclic alkanes on ozone under atmospheric conditions. The atmospheric reactivity estimates based on these mechanisms are discussed in this section.

## Scenarios Used for Reactivity Assessment

The set of airshed scenarios employed to assess the reactivities for this study is the same as those used for calculating the MIR and other reactivity scales in our previous work (Carter, 1994a), and also in the update using the SAPRC-99 mechanism (Carter, 2000). These scenarios, and the reasons for using them, are briefly described below. Note that the scenarios used in this work are exactly the same as used in the atmospheric reactivity estimates in our Phase 1 study (Carter et al, 1996).

The objective is to use a set of scenarios that represents, as much as possible, a comprehensive distribution of the environmental conditions where unacceptable levels of ozone are formed. Although a set of scenarios has not been developed for the specific purpose of VOC reactivity assessment, the EPA developed an extensive set of scenarios for conducting analyses of effects of ROG and $\mathrm{NO}_{\mathrm{x}}$ controls on ozone formation using the EKMA modeling approach (Gipson et al. 1981; Gipson and Freas, 1983; EPA, 1984; Gery et al. 1987; Baugues, 1990). The EKMA approach involves the use of single-cell box models to simulate how the ozone formation in one day episodes is affected by changes in ROG and $\mathrm{NO}_{\mathrm{x}}$ inputs. Although single-cell models cannot represent realistic pollution episodes in great detail, they can represent dynamic injection of pollutants, time-varying changes of inversion heights, entrainment of pollutants from aloft as the inversion height raises, and time-varying photolysis rates, temperatures, and humidities (Gipson and Freas, 1981; EPA, 1984; Gipson, 1984; Hogo and Gery, 1988). Thus, they can be used to simulate a wide range of the chemical conditions which affect ozone formation from ROG and $\mathrm{NO}_{\mathrm{x}}$, and which affect VOC reactivity. Therefore, at least to the extent they are suitable for their intended purpose, an appropriate set of EKMA scenarios should also be suitable for assessing reactivities over a wide range of conditions.

## Base Case Scenarios

The set of EKMA scenarios used in this study were developed by the United States EPA for assessing how various ROG and $\mathrm{NO}_{\mathrm{x}}$ control strategies would affect ozone nonattainment in various areas of the country (Baugues, 1990). The characteristics of these scenarios and the methods used to derive their input data are described in more detail elsewhere (Baugues, 1990; Carter, 1994b). Briefly, 39 urban areas in the United States were selected based on geographical representativeness of ozone nonattainment areas and data availability, and a representative high ozone episode was selected for each. The initial nonmethane organic carbon (NMOC) and $\mathrm{NO}_{\mathrm{x}}$ concentrations, the aloft $\mathrm{O}_{3}$ concentrations, and the mixing height inputs were based on measurement data for the various areas, the hourly emissions in the scenarios were obtained from the National Acid Precipitation Assessment Program emissions inventory (Baugues, 1990), and biogenic emissions were also included. Table 8 gives a summary of the urban areas represented and other selected characteristics of the scenarios.

Several changes to the scenario inputs were made based on discussions with the California ARB staff and others (Carter, 1994a,b). Two percent of the initial $\mathrm{NO}_{\mathrm{x}}$ and $0.1 \%$ of the emitted $\mathrm{NO}_{\mathrm{x}}$ in all the scenarios was assumed to be in the form of HONO. The photolysis rates were calculated using solar light intensities and spectra calculated by Jeffries (1991) for 640 meters, the approximate mid-point of the mixed layer during daylight hours. The composition of the non-methane organic pollutants entrained from aloft was based on the analysis of Jeffries et al. (1989). The composition of the initial and emitted reactive organics was derived as discussed below. Complete listings of the input data for the scenarios are given elsewhere (Carter, 1994b).

This set of 39 EKMA scenarios are referred to as "base case" to distinguish them from the scenarios derived from them by adjusting $\mathrm{NO}_{\mathrm{x}}$ inputs to yield standard conditions of $\mathrm{NO}_{\mathrm{x}}$ availability as discussed below. No claim is made as to the accuracy of these scenarios in representing any real episode, but they are a result of an effort to represent, as accurately as possible given the available data and the limitations of the formulation of the EKMA model, the range of conditions occurring in urban areas throughout the United States. When developing general reactivity scales it is more important that the scenarios employed represent a realistic distribution of chemical conditions than accurately representing the details of any one particular episode.

The Base ROG mixture is the mixture of reactive organic gases used to represent the chemical composition of the initial and emitted anthropogenic reactive organic gases from all sources in the scenarios. Consistent with the approach used in the original EPA scenarios, the same mixture was used for all scenarios. The speciation for this mixture was derived by Croes (1991) based on an analysis of the EPA database (Jeffries et al. 1989) for the hydrocarbons and the 1987 Southern California Air Quality Study (SCAQS) database for the oxygenates (Croes et al. 1994; Lurmann and Main. 1992). This mixture consists of $52 \%$ (by carbon) alkanes, $15 \%$ alkenes, $27 \%$ aromatics, $1 \%$ formaldehyde, $2 \%$ higher aldehydes, $1 \%$ ketones, and $2 \%$ acetylene. The detailed composition of this mixture is given elsewhere (Carter, 1994b; Carter, 2000).

## Adjusted $\mathrm{NO}_{\mathbf{x}}$ scenarios

Incremental reactivities in the base case scenarios would be expected to vary widely, since incremental reactivities depend on the $\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ ratio, and that ratio varies widely among the base case scenarios. To obtain reactivity scales for specified $\mathrm{NO}_{\mathrm{x}}$ conditions, separate scenarios, designated MIR (for maximum incremental reactivity), MOIR (for maximum ozone incremental reactivity), and Equal Benefit Incremental Reactivity (EBIR) were developed (Carter, 1994a). In the MIR scenarios, the $\mathrm{NO}_{\mathrm{x}}$ inputs were adjusted so the base ROG mixture (and most other VOCs) has its highest incremental reactivity. This is representative of the highest $\mathrm{NO}_{\mathrm{x}}$ conditions of relevance to VOC reactivity assessment because at higher $\mathrm{NO}_{\mathrm{x}}$ levels $\mathrm{O}_{3}$ yields become significantly suppressed, but is also the condition where $\mathrm{O}_{3}$ is most sensitive to VOC emissions. In the MOIR scenarios, the $\mathrm{NO}_{\mathrm{x}}$ inputs were adjusted to yield the highest ozone concentration. In the EBIR scenarios, the $\mathrm{NO}_{\mathrm{x}}$ inputs were adjusted so that the relative effects of $\mathrm{NO}_{\mathrm{x}}$ reductions and total ROG reductions on peak ozone levels were equal. This represents the lowest $\mathrm{NO}_{\mathrm{x}}$ condition of relevance for VOC reactivity assessment, because $\mathrm{O}_{3}$ formation becomes more sensitive to $\mathrm{NO}_{\mathrm{x}}$ emissions than VOC emissions at lower $\mathrm{NO}_{\mathrm{x}}$ levels. As discussed by Carter (1994a) the MIR and EBIR ROG/ $\mathrm{NO}_{\mathrm{x}}$ ratios are respectively $\sim 1.5$ and $\sim 0.7$ times those for the MOIR scenarios in all cases.

## $\mathrm{NO}_{\mathbf{x}}$ Conditions in the Base Case Scenarios

The variability of ROG/ $\mathrm{NO}_{\mathrm{x}}$ ratios in the base case scenarios suggests a variability of reactivity characteristics in those scenarios. However, as discussed previously (Carter, 1994a), the ROG/ $\mathrm{NO}_{\mathrm{x}}$ ratio is also variable in the MIR or MOIR scenarios, despite the fact that the $\mathrm{NO}_{\mathrm{x}}$ inputs in these scenarios are adjusted to yield a specified reactivity characteristic. Thus, the $\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ ratio, by itself, is not necessarily a good predictor of reactivity characteristics of a particular scenario. The $\mathrm{NO}_{\mathrm{x}} / \mathrm{NO}_{\mathrm{x}}{ }^{\text {MOIR }}$ ratio is a much better predictor of this, with values greater than 1 indicating relatively high $\mathrm{NO}_{\mathrm{x}}$ conditions where ozone formation is more sensitive to VOCs, and values less than 1 indicating $\mathrm{NO}_{\mathrm{x}}$-limited conditions. $\mathrm{NO}_{\mathrm{x}} / \mathrm{NO}_{\mathrm{x}}{ }^{\text {MOIR }}$ ratios less than 0.7 represent conditions where $\mathrm{NO}_{\mathrm{x}}$ control is a more effective ozone control strategy than ROG control (Carter, 1994a). Note that more than half of the base case scenarios represent $\mathrm{NO}_{\mathrm{x}}$-limited conditions, and $\sim 25 \%$ of them represent conditions where $\mathrm{NO}_{\mathrm{x}}$ control is more beneficial than VOC control. A relatively small number of scenarios represent MIR or near MIR conditions. However, as discussed elsewhere (Carter, 1994a), this set of scenarios is based on near-worstcase conditions for ozone formation in each of the airsheds. Had scenarios representing less-than-worstcase conditions been included, one might expect a larger number of MIR or near MIR scenarios. This is because $\mathrm{NO}_{\mathrm{x}}$ is consumed more slowly on days with lower light intensity or temperature, and thus the scenario is less likely to become $\mathrm{NO}_{\mathrm{x}}$-limited.

## Quantification of Atmospheric Reactivity

The reactivity of a VOC in an airshed scenario is measured by its incremental reactivity. For ambient scenarios, this is defined as the change in ozone caused by adding the VOC to the emissions,
divided by the amount of VOC added, calculated for sufficiently small amounts of added VOC that the incremental reactivity is independent of the amount added ${ }^{1}$.

$$
\begin{equation*}
\operatorname{IR}(\text { VOC, Scenario })=\lim _{\text {VOC } \rightarrow 0}\left[\frac{\mathrm{O}_{3}(\text { Scenario with VOC added })-\mathrm{O}_{3}(\text { Base Scenario })}{\text { Amount of VOC Added }}\right] \tag{V}
\end{equation*}
$$

The specific calculation procedure is discussed in detail elsewhere (Carter, 1994a,b).

Incremental reactivities derived as given above tend to vary from scenario to scenario because they differ in their overall sensitivity of $\mathrm{O}_{3}$ formation to VOCs. These differences can be factored out to some extent by using "relative reactivities", which are defined as ratios of incremental reactivities to the incremental reactivity of the base ROG mixture, which is used to represent emissions of reactive VOCs from all sources.

$$
\begin{equation*}
\mathrm{RR}(\text { VOC,Scenario })=\frac{\mathrm{IR}(\text { VOC, Scenario })}{\operatorname{IR}(\text { Base ROG, Scenario })} \tag{VI}
\end{equation*}
$$

These relative reactivities can also be thought of as the relative effect on $\mathrm{O}_{3}$ of controlling emissions of the particular VOC by itself, compared to controlling emissions from all VOC sources equally. Thus, they are more meaningful in terms of control strategy assessment than absolute reactivities, which can vary greatly depending on the episode and local meteorology.

In addition to depending on the VOC and the scenario, the incremental and relative reactivities depend on how the amounts of VOC added are quantified. In this work, this is quantified on a mass basis, since this is how VOCs are regulated, and generally approximates how VOC substitutions are made in practice. Note that relative reactivities will be different if they are quantified on a molar basis, with VOCs with higher molecular weight having higher reactivities on a mole basis than a gram basis.

Relative reactivities can also depend significantly on how ozone impacts are quantified (Carter, 1994a). Two different ozone quantification methods are used in this work, as follows:
"Ozone Yield" reactivities measure the effect of the VOC on the total amount of ozone formed in the scenario at the time of its maximum concentration. Incremental reactivities are quantified as grams $\mathrm{O}_{3}$ formed per gram VOC added. Most previous recent studies of ozone reactivity (Dodge, 1984; Carter and Atkinson, 1987, 1989, Chang and Rudy, 1990; Jeffries and Crouse, 1991) have been based on this quantification method. The MIR, MOIR, and EBIR scales of Carter (1994a) also use this quantification.
"Maximum 8 Hour Average" reactivities measure the effect of the VOC on the average ozone concentration during the 8 -hour period when the average ozone concentration was the greatest, which in

[^0]these one-day scenarios was the last 8 hours of the simulation. This provides a measure of ozone impact that is more closely related to the new Federal ozone standard that is given in terms of an 8 -hour average. This quantification is used for relative reactivities in this work.

In previous reports, we have reported reactivities in terms of integrated $\mathrm{O}_{3}$ over a standard concentration of 0.09 or 0.12 ppm . This provides a measure of the effect of the VOC on exposure to unacceptable levels of ozone. This is replaced by the maximum 8-hour average reactivities because it is more representative of the proposed new Federal ozone standard and because reactivities relative to integrated $\mathrm{O}_{3}$ over a standard tend to be between those relative to ozone yield and those relative to 8-hour averages. Therefore, presenting both ozone yield and maximum 8 -hour average relative reactivities should be sufficient to provide information on how relative reactivities vary with ozone quantification method. Incremental reactivities are quantified as $\mathrm{ppm}_{3}$ per milligram VOC emitted per square meter, but maximum 8 -hour average reactivities are usually quantified as relative reactivities quantified on a mass basis.

Note that incremental reactivities are calculated for a total of 156 scenarios, consisting of the 39 base case scenarios and the three adjusted $\mathrm{NO}_{\mathrm{x}}$ scenarios for each of the 39 base case scenarios. However, the incremental reactivities in the MIR, MOIR, or EBIR) scales are reported as averages of the incremental reactivities in the corresponding adjusted $\mathrm{NO}_{\mathrm{x}}$ scenarios, because adjusting the $\mathrm{NO}_{\mathrm{x}}$ conditions reduces the scenario variability, and this allows for a derivation single reactivity scales representing each type of $\mathrm{NO}_{\mathrm{x}}$ condition. On the other hand, the individual scenario results will be shown for the base case scenarios, to give an indication of the scenario-to-scenario variability of the calculated reactivity results.

## Results

Table 9 lists the ozone yield incremental reactivities calculated for selected represented $\mathrm{C}_{12}-\mathrm{C}_{16}$ normal and cyclic alkanes, ethane, and the mixture of emitted reactive organic compounds (the base ROG). Table 10 gives the ozone yield and Table 11 gives maximum 8-hour average reactivities relative to the base ROG for these compounds and also for acetone. Ethane is chosen for comparison because it has been used by the EPA as the informal standard to determine "negligible" reactivity for VOC exemption purposes (Dimitriades, 1999). Acetone is also shown because it is a compound of similar reactivity as ethane that has been exempted from regulation as an ozone precursor. Distribution plots of the relative reactivities of ethane and selected $\mathrm{C}_{\geq 12}$ normal and cyclic alkanes are shown on Figure 9 through Figure 12 for the base case, MIR, MOIR, and EBIR scenarios, respectively.

The results show that the incremental and relative reactivities of these $\mathrm{C}_{\geq 12}$ normal and branched alkanes are highly variable and dependent on scenario conditions and on how ozone impacts are quantified. This variability cannot be attributed to variability in $\mathrm{NO}_{\mathrm{x}}$ conditions alone since, as can be seen from Figure 10 through Figure 12, relatively wide distributions of the $\mathrm{C}_{\geq 12}$ alkane relative reactivities are observed in the adjusted $\mathrm{NO}_{\mathrm{x}}$ scenarios. By comparison, ethane (and most other VOCs) has much

Table 9. Atmospheric incremental calculated for the base ROG mixture, ethane, and selected $\mathrm{C}_{\geq 12}$ normal and cyclic alkanes.

narrower distributions of relative reactivities once the $\mathrm{NO}_{x}$ conditions have been adjusted. However, the average relative reactivities of the $\mathrm{C}_{\geq 12}$ alkanes tend to decrease with decreasing $\mathrm{NO}_{\mathrm{x}}$ conditions, with the average relative reactivities being highest in the high $\mathrm{NO}_{\mathrm{x}}$ MIR scenarios, and lowest in the base case scenarios, which include many scenarios with lower than EBIR $\mathrm{NO}_{\mathrm{x}}$ levels.

The highly variable relative reactivities of the $\mathrm{C}_{\geq 12}$ alkane can be explained by considering the different factors affecting their reactivities. The higher alkanes have a large positive effect on $\mathrm{O}_{3}$ formation in that they react relatively rapidly and form a relatively large number of peroxy radicals that convert NO to $\mathrm{NO}_{2}$. This positive impact is important under all $\mathrm{NO}_{\mathrm{x}}$ conditions, though the efficiency of $\mathrm{O}_{3}$ formation from NO to $\mathrm{NO}_{2}$ conversions tends to decrease as $\mathrm{NO}_{\mathrm{x}}$ levels decrease (Carter and Atkinson, 1989b). This positive effect is counteracted by the radical inhibition and $\mathrm{NO}_{\mathrm{x}}$ removal processes caused by the nitrate formation reaction. Under high $\mathrm{NO}_{x}$ MIR conditions, it is the radical inhibition factor that is dominant, and the variability of overall reactivity from scenario to scenario is due to the variability of the relative importance of the radical inhibition vs. direct NO to $\mathrm{NO}_{2}$ conversion effects. The $\mathrm{NO}_{\mathrm{x}}$ removal effect of the nitrate formation reaction is unimportant. However, under low $\mathrm{NO}_{\mathrm{x}}$ conditions, the $\mathrm{NO}_{\mathrm{x}}$ removal factor becomes much more important than the radical inhibition factor, and thus the variability is due to the varying balance between this factor and the direct NO to $\mathrm{NO}_{2}$ conversions.

It is interesting to note that the relative reactivities of the $\mathrm{C}_{212}$ alkanes tend to be considerably less when ozone is quantified by the maximum 8 -hour average than is the case when it is quantified by peak $\mathrm{O}_{3}$ yields. The difference between the ozone yield and the 8-hour average relative reactivities increase with $\mathrm{NO}_{\mathrm{x}}$ conditions. For example, the 8 -hour average relative reactivities for the $\mathrm{C}_{\geq 12}$ alkanes are about $40 \%$ higher in the MIR scenarios, about a factor of 2-4 higher in the MOIR scenarios, and in many cases negative in the EBIR scenarios. Apparently $\mathrm{NO}_{\mathrm{x}}$ and radical inhibition effects tend to be more important in affecting average ozone levels than they are in affecting peak ozone yields.

In terms of comparing the individual n-alkane compounds, the calculations indicate that, as expected, the ozone impact decreases monotonically as the size of the compound increases. This is attributed to the fact that the nitrate yields decrease as the size of the molecule increase. In addition, the alkyl cyclohexanes tend to have somewhat higher reactivities, by about $5-25 \%$ on the average, than their normal alkane isomers. This is attributed to the somewhat larger number of NO to $\mathrm{NO}_{2}$ conversions estimated to occur in the overall reactions of the alkyl cyclohexanes, as shown on Table 2, above. It cannot be due to differences in nitrate formation, since the overall nitrate yields for the alkyl cyclohexanes are slightly higher than from their normal alkane isomers (see Table 2).

The data are ambiguous in terms of the reactivities of these $\mathrm{C}_{\geq 12}$ alkanes relative to ethane. No matter which ozone quantifications or $\mathrm{NO}_{\mathrm{x}}$ levels are considered, there are scenarios where the $\mathrm{C}_{\geq 12}$ alkane form more ozone than does an equal mass of ethane, and there are others where they either form less ozone or actually inhibit ozone levels. In terms of averages, the impacts of the $\mathrm{C}_{\geq 12}$ alkanes on
maximum 8-hour average ozone levels are less than those of ethane under most conditions, while their impacts on peak ozone yields tend to be greater than ethane, except for the lower $\mathrm{NO}_{\mathrm{x}}$ base case scenarios.

It is interesting to note that the average reactivities of the $\mathrm{C}_{\geq 12}$ alkanes relative to ethane tend to be lower in the base case scenarios than in any of the adjusted $\mathrm{NO}_{\mathrm{x}}$ scenarios. This is because many of the base case scenarios have lower relative $\mathrm{NO}_{\mathrm{x}}$ levels than the lowest adjusted $\mathrm{NO}_{\mathrm{x}}$, EBIR scenarios. As indicated above, the relative $\mathrm{NO}_{x}$ levels of a scenario can be measured by the ratio of the $\mathrm{NO}_{\mathrm{x}}$ inputs to the $\mathrm{NO}_{\mathrm{x}}$ inputs yield the maximum ozone levels (the MOIR $\mathrm{NO}_{\mathrm{x}}$ ). It can be seen that a substantial number of base case scenarios have $\mathrm{NO}_{\mathrm{x}}$ levels lower than EBIR, and it is these scenarios where the ozone yield reactivities tend to be lower than that for ethane or negative. Indeed, $n$-dodecane is calculated to have ozone yield reactivities less than that of ethane, and also to have negative maximum 8-hour average reactivities, for all scenarios where the $\mathrm{NO}_{\mathrm{x}}$ levels are less than half that of MOIR levels. The $\mathrm{NO}_{\mathrm{x}}$ dependence of the reactivities relative to $\mathrm{NO}_{\mathrm{x}}$ is relatively small when $\mathrm{NO}_{\mathrm{x}}$ is above EBIR levels, and other aspects of the scenarios appear to be relatively more important in determining reactivities relative to ethane. The specific factors that are the most important in this regard have not been identified.

Figure 13. Plots of reactivities of n-dodecane relative to ethane in the base case scenarios against the ratio of $\mathrm{NO}_{\mathrm{x}}$ inputs to the MOIR $\mathrm{NO}_{\mathrm{x}}$ inputs.

## CONCLUSIONS

The decision whether it is appropriate to regulate a group of compounds as ozone precursors requires a qualitative assessment of their ozone impacts under a variety of environmental conditions. This requires developing mechanisms for the relevant reactions of the subject compounds, verifying that the mechanisms can accurately predict the impacts of these compounds on ozone formation and other relevant measures or reactivity, and then using the mechanisms in airshed models to predict the impacts in representative atmospheric scenarios. Although estimated mechanisms for the higher alkanes have been available for some time (Carter, 1990), until the first phase of this project there have been no data to test the predictive capabilities of estimated mechanisms for the higher $\left(\mathrm{C}_{\geq 12}\right) \mathrm{n}$-alkanes, and until the second phase there were no data to test the mechanisms for the higher cycloalkanes. This project has been successful in providing the data needed to test the mechanisms for those compounds, allowing their atmospheric impacts to be predicted to a greater degree of reliability than was previously the case.

The alkane mechanisms derived using the estimation procedures and mechanism generation system associated with the SAPRC-99 mechanism (Carter, 2000) have been shown to give predictions that are consistent with the environmental chamber data obtained in both phases of this project. No adjustments had to be made to the estimated mechanisms to obtain the fits to attain successful model simulations of these data. The environmental chamber data represent a reasonable range of conditions in terms of relative $\mathrm{NO}_{\mathrm{x}}$ levels, sensitivity of the mixture to radical levels, and the nature of the light source, which means that the testing of the mechanisms were reasonably comprehensive. Based on this, we conclude that the SAPRC-99 mechanism will probably give reasonably reliable predictions of the impacts of the $\mathrm{C}_{12}-\mathrm{C}_{16} \mathrm{n}$-alkanes and of the $\mathrm{C}_{12}-\mathrm{C}_{14} \mathrm{n}$-alkyl cyclohexanes on ozone formation and other measures of reactivity in the atmosphere, if the relevant scenario conditions are appropriately represented. Note that this mechanism has some substantial differences with the mechanisms used in our previous studies, and thus the alkane reactivity estimates in the Phase 1 report of Carter et al (1996) are superceded by this work.

It should be pointed out, however, that the available data do not definitively validate the mechanisms for all the higher alkane compounds. Because of experimental problems with handling low volatility compounds, data could not be obtained on normal alkanes heavier than n-hexadecane, even though such compounds still have sufficient volatility to react in the gas phase in the atmosphere, and contribute to ozone formation. However, based on the trends observed in this work and based on theoretical considerations, one would expect the $\mathrm{C}_{>16} \mathrm{n}$-alkanes to be no more reactive than n-hexadecane, with the only uncertainty being how much less reactive they are. Thus if n-hexadecane is concluded to have "negligible" reactivity, it is probably reasonably safe to conclude that this is the case for the higher n-alkanes as well.

The situation is somewhat more uncertain in the case of the estimated reactivities of the branched and cyclic alkanes. The branched alkanes were not studied in this work, though data obtained under
separate funding indicated that the estimated mechanisms perform reasonably well in simulating results of experiments with several $\mathrm{C}_{10}$ branched alkanes (Carter et al, 2000b; Carter, 2000). A wide variety of branched and cyclic alkane isomers are possible for the higher carbon numbers, and it is only practical to study a small subset of the large number of possibilities. Although the data obtained in this project indicate that the mechanisms perform reasonably well for the $n$-alkyl cyclohexanes, data were not obtained to test the mechanisms derived for more branched cycloalkanes such as compounds with more than one substituent around the ring, or more than one ring. Therefore, reactivity estimates for unspeciated cyclic alkanes must necessarily be considered more uncertain. This would also be the case for the branched alkanes, though Carter et al (2000b) did obtain data on isomers with differing degrees of branching, though not with varying molecular weights.

Consistent with predictions using previous mechanisms (Carter, 1994a; Carter et al, 1996), the atmospheric ozone impacts for the higher alkanes were found to be highly dependent on conditions, both in an absolute sense and also relative to other VOCs such as ethane. Because of their strong radical inhibiting characteristics the $\mathrm{C}_{\geq 12}$ alkanes were calculated to have relatively low ozone impacts, with ozone formation on a mass basis usually being less than $25 \%$ that of the mixture of compounds representing VOC emissions from all sources. However, the impacts relative to ethane, the compound that has been used as the standard defining "negligible" reactivity for VOC exemption purposes, are highly variable, depending not only on scenario conditions but also on how ozone impacts are quantified. In general, the relative ozone impacts of the higher alkanes are lower in scenarios with lower $\mathrm{NO}_{\mathrm{x}}$ conditions (especially below EBIR levels) and the relative impacts on the maximum 8-hour average ozone tend to be lower (much lower some cases) than relative impacts on peak ozone yields. In general, the impacts of the $\mathrm{C}_{\geq 12}$ alkanes on maximum 8-hour average ozone levels are less than those of ethane under most conditions, while their impacts on peak ozone yields tend to be greater than ethane, except for the lower $\mathrm{NO}_{\mathrm{x}}$ base case scenarios. However, the results are highly variable and dependent on other scenario conditions besides $\mathrm{NO}_{x}$.

Because of the relatively large dependence in calculated relative reactivities of the $\mathrm{C}_{\geq 12}$ alkanes with scenario conditions, it is important that the set of scenarios used to assess their relative reactivities be reasonably representative of the distribution of conditions in the atmosphere. Although the EKMA scenarios used for the reactivity assessments in this work were designed to represent a range of conditions, they are obviously highly simplified representations of real urban areas. These simplifications are somewhat less of a concern when assessing ozone impacts of VOCs whose relative reactivities depend primarily on $\mathrm{NO}_{\mathrm{x}}$, since the use of the adjusted $\mathrm{NO}_{\mathrm{x}}$ scenarios permit these $\mathrm{NO}_{\mathrm{x}}$ effects to be systematically assessed. However, it is clear that other scenario conditions are affecting relative reactivities for the $\mathrm{C}_{\geq 12}$ alkanes much greater than is the case for other VOCs, particularly at $\mathrm{NO}_{\mathrm{x}}$ levels above EBIR, where VOC control is more effective than $\mathrm{NO}_{\mathrm{x}}$ control for reducing ozone. Because of this, it may be appropriate to determine which scenario conditions are the most important in affecting predicted relative reactivities of these compounds, and to assure that the scenarios used to assess their reactivities represent these conditions appropriately.

## APPENDIX A. <br> MECHANISM LISTING AND TABULATIONS

This Appendix gives a complete listing of the mechanisms used in the model simulations in this report. Table A-1 contains a list of all the model species used in the mechanism, and Table A-2 lists the reactions and rate parameters, and Table A-3 lists the absorption cross sections and quantum yields for the photolysis reactions. In addition, Finally, Table A-4 gives the chamber-dependent parameters used in the model simulations of the chamber experiments.

Table A-1. Listing of the model species in the mechanism used in the model simulations discussed in this report.

Type and Name Description

## Species used in Base Mechanism

Constant Species.

| O2 | Oxygen |
| :--- | :--- |
| M | Air |
| H2O | Water |
| H2 | Hydrogen Molecules |
| HV | Light |

Active Inorganic Species.

| O3 | Ozone |
| :--- | :--- |
| NO | Nitric Oxide |
| NO2 | Nitrogen Dioxide |
| NO3 | Nitrate Radical |
| N2O5 | Nitrogen Pentoxide |
| HONO | Nitrous Acid |
| HNO3 | Nitric Acid |
| HNO4 | Peroxynitric Acid |
| HO2H | Hydrogen Peroxide |
| CO | Carbon Monoxide |
| SO2 | Sulfur Dioxide |

Active Radical Species and Operators.
HO. Hydroxyl Radicals
HO2. Hydroperoxide Radicals
C-O2. Methyl Peroxy Radicals
RO2-R. Peroxy Radical Operator representing NO to NO2 conversion with HO 2 formation.
R2O2. Peroxy Radical Operator representing NO to NO 2 conversion without HO 2 formation.
RO2-N. Peroxy Radical Operator representing NO consumption with organic nitrate formation.
CCO-O2. Acetyl Peroxy Radicals
RCO-O2. Peroxy Propionyl and higher peroxy acyl Radicals

Table A-1 (continued)

| Type and Name | Description |
| :---: | :---: |
| BZCO-O2. | Peroxyacyl radical formed from Aromatic Aldehydes |
| MA-RCO3. | Peroxyacyl radicals formed from methacrolein and other acroleins. |
| Steady State Radical Species |  |
| O3P | Ground State Oxygen Atoms |
| O*1D2 | Excited Oxygen Atoms |
| TBU-O. | t-Butoxy Radicals |
| BZ-O. | Phenoxy Radicals |
| BZ(NO2)-O. | Nitro-substituted Phenoxy Radical |
| HOCOO. | Radical formed when Formaldehyde reacts with HO2 |
| PAN and PAN Analogues |  |
| PAN | Peroxy Acetyl Nitrate |
| PAN2 | PPN and other higher alkyl PAN analogues |
| PBZN | PAN analogues formed from Aromatic Aldehydes |
| MA-PAN | PAN analogue formed from Methacrolein |
| Explicit and Lumped Molecule Reactive Organic Product Species |  |
| HCHO | Formaldehyde |
| CCHO | Acetaldehyde |
| RCHO | Lumped C3+ Aldehydes |
| ACET | Acetone |
| MEK | Ketones and other non-aldehyde oxygenated products that react with OH radicals slower than $5 \times 10^{-12} \mathrm{~cm}^{3} \mathrm{molec}^{-2} \mathrm{sec}^{-1}$. |
| MEOH | Methanol |
| COOH | Methyl Hydroperoxide |
| ROOH | Lumped higher organic hydroperoxides |
| GLY | Glyoxal |
| MGLY | Methyl Glyoxal |
| BACL | Biacetyl |
| PHEN | Phenol |
| CRES | Cresols |
| NPHE | Nitrophenols |
| BALD | Aromatic aldehydes (e.g., benzaldehyde) |
| METHACRO | Methacrolein |
| MVK | Methyl Vinyl Ketone |
| ISO-PROD | Lumped isoprene product species |
| Lumped Parameter Products |  |
| PROD2 | Ketones and other non-aldehyde oxygenated products that react with OH radicals faster than $5 \times 10^{-12} \mathrm{~cm}^{3}$ molec $^{-2} \mathrm{sec}^{-1}$. |
| RNO3 | Lumped Organic Nitrates |
| Uncharacterized Reactive Aromatic Ring Fragmentation Products |  |
| DCB1 | Reactive Aromatic Fragmentation Products that do not undergo significant photodecomposition to radicals. |
| DCB2 | Reactive Aromatic Fragmentation Products which photolyze with alpha-dicarbonyl-like action spectrum. |
| DCB3 | Reactive Aromatic Fragmentation Products which photolyze with acrolein action spectrum. |

Table A-1 (continued)

| Type and Name | Description |
| :---: | :---: |
| Non-Reacting Species |  |
| CO 2 | Carbon Dioxide |
| XC | Lost Carbon |
| XN | Lost Nitrogen |
| SULF | Sulfates ( $\mathrm{SO}_{3}$ or $\mathrm{H}_{2} \mathrm{SO}_{4}$ ) |
| Low Reactivity Compounds or Unknown Products Represented as Unreactive |  |
| H2 | Hydrogen |
| HCOOH | Formic Acid |
| CCO-OH | Acetic Acid |
| RCO-OH | Higher organic acids |
| CCO-OOH | Peroxy Acetic Acid |
| RCO-OOH | Higher organic peroxy acids |
| NROG | Unspecified Unreactive Carbon |
| Base ROG VOC Species used in the Chamber Simulations |  |
| N-C4 | n-Butane |
| N-C6 | n -Hexane |
| N-C8 | n-Octane |
| ETHENE | Ethene |
| PROPENE | Propene |
| T-2-BUTE | Trans-2-Butene |
| TOLUENE | Toluene |
| M-XYLENE | m-Xylene |
| Test Compounds Studied for this Project |  |
| N-C12 | n-Dodecane |
| N-C14 | n -Tetradecane |
| N-C15 | n-Pentadecane |
| N-C16 | n-Hexadecane |
| C6-CYCC6 | Hexyl Cyclohexane |
| C8-CYCC6 | Octyl Cyclohexane |
|  | Lumped Higher Ketone Products from the Alkane Test Compounds |
| PRD-NC12 | Lumped higher ketones formed in the reaction of OH with n -dodecane. The compounds represented by this model species are listed in Table 3. |
| PRD-NC14 | Lumped higher ketones formed in the reaction of OH with n-tetradecane. The compounds represented by this model species are analogous to those listed in Table 3 for n -dodecane. |
| PRD-NC15 | Lumped higher ketones formed in the reaction of OH with n-pentadecane. The compounds represented by this model species are analogous to those listed in Table 3 for n -dodecane. |
| PRD-NC16 | Lumped higher ketones formed in the reaction of OH with n-hexadecane. The compounds represented by this model species are analogous to those listed in Table 3 for n -dodecane. |
| PRD-CC12 | Lumped higher ketones formed in the reaction of OH with hexyl cyclohexane. The compounds represented by this model species are listed in Table 3. |

Table A-1 (continued)

| Type and Name | Description |
| :---: | :---: |
| PRD-CC14 | Lumped higher ketones formed in the reaction of OH with octyl cyclohexane. The compounds represented by this model species are analogous to those listed in Table 3 for hexyl cyclohexane. |
| Explicit and Lumped VOC Species used in the Ambient Simulations |  |
| Primary Organics Represented explicitly |  |
| CH4 | Methane |
| ETHENE | Ethene |
| ISOPRENE | Isoprene |
| Example Test VOCs not in the Base Mechanism |  |
| ETHANE | Ethane |
| Lumped Parameter Species |  |
| ALK1 | Alkanes and other non-aromatic compounds that react only with OH , and have $\mathrm{kOH}<5$ $\times 10^{2} \mathrm{ppm}-1 \mathrm{~min}-1$. (Primarily ethane) |
| ALK2 | Alkanes and other non-aromatic compounds that react only with OH , and have kOH between $5 \times 10^{2}$ and $2.5 \times 10^{3} \mathrm{ppm}-1 \mathrm{~min}-1$. (Primarily propane and acetylene) |
| ALK3 | Alkanes and other non-aromatic compounds that react only with OH , and have kOH between $2.5 \times 10^{3}$ and $5 \times 10^{3} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| ALK4 | Alkanes and other non-aromatic compounds that react only with OH , and have kOH between $5 \times 10^{3}$ and $1 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| ALK5 | Alkanes and other non-aromatic compounds that react only with OH , and have kOH greater than $1 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| ARO1 | Aromatics with $\mathrm{kOH}<2 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| ARO2 | Aromatics with $\mathrm{kOH}>2 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| OLE1 | Alkenes (other than ethene) with $\mathrm{kOH}<7 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| OLE2 | Alkenes with $\mathrm{kOH}>7 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| TERP | Terpenes |

Table A-2. Listing of the reactions in the mechanism used in the model simulations discussed in this report. See Carter (2000) for documentation.

[a] Except as indicated, the rate constants are given by $k(T)=A \cdot(T / 300)^{B} \cdot e^{-E a / R T}$, where the units of $k$ and $A$ are $\mathrm{cm}^{3}$ molec $^{-1} \mathrm{~s}^{-1}$, Ea are kcal mol ${ }^{-1}$, T is ${ }^{\circ} \mathrm{K}$, and $\mathrm{R}=0.0019872 \mathrm{kcal} \mathrm{mol}^{-1} \mathrm{deg}^{-1}$. The following special rate constant expressions are used: Phot Set = name: The absorption cross sections and quantum yields for the photolysis reaction are given in Table A-3, where "name" indicates the photolysis set used. If a "qy=number" notation is given, the number given is the overall quantum yield, which is assumed to be wavelength independent. Falloff: The rate constant as a function of temperature and pressure is calculated using $\mathrm{k}(\mathrm{T}, \mathrm{M})=$ $\{\mathrm{k} 0(\mathrm{~T}) \cdot[\mathrm{M}] /[1+\mathrm{k} 0(\mathrm{~T}) \cdot[\mathrm{M}] / \operatorname{kinf}(\mathrm{T})]\} \cdot \mathrm{F}^{\mathrm{Z}}$, where $\left.\mathrm{Z}=\left\{1+\left[\log _{10}\{\mathrm{k} 0(\mathrm{~T}) \cdot[\mathrm{M}]) / \operatorname{kinf}(\mathrm{T})\right\}\right]^{2}\right\}^{-1},[\mathrm{M}]$ is the total pressure in molecules $\mathrm{cm}^{-3}, \mathrm{~F}$ is as indicated on the table, and the temperature dependences of k 0 and kinf are as indicated on the table. (Slow): The reaction is assumed to be negligible and is not included in the mechanism. It is shown on the listing for documentation purposes only. $k=k 0+\mathrm{k} 3 \mathrm{M}(1+\mathrm{k} 3 \mathrm{M} / \mathrm{k} 2)$ : The rate constant as a function of temperature and pressure is calculated using $k(T, M)=k 0(T)+k 3(T) \cdot[\mathrm{M}] \cdot(1+$ $\mathrm{k} 3(\mathrm{~T}) \cdot[\mathrm{M}] / \mathrm{k} 2(\mathrm{~T})$ ), where $[\mathrm{M}]$ is the total bath gas (air) concentration in molecules $\mathrm{cm}^{-3}$, and the temperature dependences for $\mathrm{k} 0, \mathrm{k} 2$ and k 3 are as indicated on the table. $\mathrm{k}=\mathrm{k} 1+\mathrm{k} 2[\mathrm{M}]$ : The rate constant as a function of temperature and pressure is calculated using $\mathrm{k}(\mathrm{T}, \mathrm{M})=\mathrm{k} 1(\mathrm{~T})+\mathrm{k} 2(\mathrm{~T}) \cdot[\mathrm{M}]$, where $[\mathrm{M}]$ is the total bath gas (air) concentration in molecules $\mathrm{cm}^{-3}$, and the temperature dependences for k 1 , and k 2 are as indicated on the table. Same k as Rxn label: The rate constant is the same as the reaction with the indicated label.
[b] Format of reaction listing: "=" separates reactants from products; "\#number" indicates stoichiometric coefficient, "\#coefficient \{ product list \}" means that the stoichiometric coefficient is applied to all the products listed. See Table A-1 for a listing of the model species used.
[c] Mechanisms for the alkanes derived using the SAPRC-99 mechanism generation system, with measured rate constant. Mechanisms for the lumped higher ketone product model species were derived by weighted averages of the estimated mechanisms derived for the individual product compounds See Carter (2000) for a discussion of adjusted product mechanisms.

Table A-3. Listing of the absorption cross-sections and quantum yields for the photolysis reactions.

Table A-4. Chamber wall effect and background characterization parameters used in the environmental chamber model simulations for mechanism evaluation.

| Cham. | Set [a] | Value | Discussion |
| :---: | :---: | :---: | :---: |
| $\underline{\mathrm{RN}-\mathrm{I}}$ (ppb) |  |  | Ratio of the rate of wall $\boldsymbol{+} \mathbf{h} \boldsymbol{v}->\mathbf{H O N O}$ to the $\mathrm{NO}_{2}$ photolysis rate. <br> Average of value of RS-I that gave best fits to n-butane - NOx chamber experiments carried out in this chamber. The initial HONO was optimized at the same time. If a temperature dependence is shown, it was derived from the temperature dependence of the RN-I values that best fit characterization data in outdoor chamber experiments, with the same activation energy used in all cases. If a temperature dependence is not shown, then the temperature variation for experiments in this set is small compared to the run-to-run variability in the best fit RN-I values. Note that the radical source in Sets 3, 12, 13, and 16 runs was anomalously high. Any dependence of apparent radical source on initial NOx levels in Teflon bag chambers was found to be much less than the run-to-run variability. |
| DTC | $\begin{aligned} & 10 \\ & 11 \end{aligned}$ | $\begin{array}{r} 8.14 \mathrm{e}+9 \exp (- \\ 0.080 \end{array}$ |  |
| CTC | $\begin{gathered} \leq 7 \\ 9 \end{gathered}$ | $\begin{aligned} & 0.064 \\ & 0.097 \end{aligned}$ | Same procedure as for the DTC. The runs in Set 9 had slightly higher radical source than most other CTC experiments, so a slightly higher radical source parameter is used for those runs. |
| HONO-F (unitless) |  |  | Ratio of the initial HONO concentration to the measured initial NO2. [The initial NO2 in the experiment is reduced by a factor of $1-$ (HONO-F)]. Unless the characterization data indicate otherwise, it is assumed that the initial HONO is introduced with the NO 2 injection, so is it is assumed to be proportional to the initial NO 2 concentration. |
| DTC | $\begin{aligned} & 10 \\ & 11 \end{aligned}$ | $\begin{aligned} & 0.8 \% \\ & 0.6 \% \end{aligned}$ | Average of value of initial HONO to initial NO2 that gave best fits to nbutane - NOx chamber experiments carried out in this chamber. The RN-I parameter was optimized at the same time. |
| CTC | All | 0.08 | Same procedure as for CTC |
| E-NO2 | K1 (ppb) |  | Ratio of rate of NO2 offgasing from the walls to the NO 2 photolysis rate. |
| All Te <br> Chamb | on Bag | 0 | The NOx offgasing caused by representing the radical source by HONO offgasing appears to be sufficient for accounting for NOx offgasing effects in most cases. RN-I parameters adjusted to fit experiments sensitive to the radical source are consistent with NOx offgasing rates adjusted to fit pure air or aldehyde - air runs, to within the uncertainty and variability. |
| K(NO2 | V) (m |  | Rate of unimolecular loss (or hydrolysis) of NO2 to the walls. |
| All Te <br> Cham | on Bag | $1.6 \mathrm{e}-4$ | Based on dark NO2 decay and HONO formation measured in the ETC by Pitts et al. (1984). Assumed to be the same in all Teflon bag chambers, regardless of volume. |
| YHON |  |  | Yield of HONO in the unimolecular reaction (hydrolysis) of NO2 on the walls. |
| All Te <br> Chamb | on Bag | 0.2 | Based on dark NO2 decay and HONO formation measured in the ETC by Pitts et al. (1984). Assumed to be the same in all Teflon bag chambers, regardless of volume. |
| K(O3W | $\left(\mathrm{min}^{-1}\right)$ |  | Unimolecular loss rate of O 3 to the walls. |
| DTC | All | $1.5 \mathrm{e}-4$ | Based on results of $\mathrm{O}_{3}$ decay in Teflon bag chambers experiments as discussed by Carter et al (1995c). |
| CTC | All | $8.5 \mathrm{e}-5$ | Based on results of $\mathrm{O}_{3}$ decay experiments in this chamber |

Table A-4 (continued)

| Cham. Set [a] | Value | Discussion |
| :---: | :---: | :---: |
| $\underline{\mathrm{k}}$ (N26I) ( $\mathrm{min}^{-1}$ ) |  | Rate constant for $\mathbf{N} 2 \mathrm{O5}$-> $\mathbf{2}$ Wall-NOx. This represents the humidityindependent portion of the wall loss of $\mathrm{N}_{2} \mathrm{O}_{5}$, or the intercept of plots of rates of $\mathrm{N}_{2} \mathrm{O}_{5}$ loss against humidity. |
| All Teflon Bag Chambers | 2.8e-3 | Based on $\mathrm{N}_{2} \mathrm{O}_{5}$ decay rate measurements made by Tuazon et al (1983) for the ETC. Assumed to be independent of chamber size (Carter et al, 1995c). |
| $\underline{\mathrm{k}(\mathrm{N} 26 \mathrm{~S})\left(\mathrm{ppm}^{-1} \mathrm{~min}^{-1}\right)}$ |  | Rate constant for $\mathbf{N} 2 \mathrm{O} 5+\mathbf{H 2 O}$-> $\mathbf{2}$ Wall-NOx. This represents the humidity dependent portion of the wall loss of $\mathrm{N}_{2} \mathrm{O}_{5}$, or the slope of plots of rates of $\mathrm{N}_{2} \mathrm{O}_{5}$ loss against humidity. |
| All Teflon Bag Chambers | 1.1e-6 | Based on $\mathrm{N}_{2} \mathrm{O}_{5}$ decay rate measurements made by Tuazon et al (1983) for the ETC. Assumed to be independent of chamber size (Carter et al, 1995c). |
| $\underline{\mathrm{k}(\mathrm{XSHC})\left(\mathrm{min}^{-1}\right)}$ |  | Rate constant for $\mathbf{O H}$-> HO2. This represents the effects of reaction of OH with reactive VOCs in the background air or offgased from the chamber walls. This parameter does not significantly affect model simulations of experiments other than pure air runs. |
| All Teflon Bag Chambers | 250 | Estimated from modeling several pure air in the ITC (Carter et al, 1996d), and also consistent with simulations of pure air runs in the ETC (Carter et al, 1997a). |
| $\underline{\mathrm{H} 2 \mathrm{O}}$ (ppm) |  | Default water vapor concentration for runs where no humidity data are available. |
| $\begin{aligned} & \text { DTC all } \\ & \text { CTC } \end{aligned}$ | $1.0 \mathrm{e}+3$ | Experiments in this chamber were carried out using dried purified air. The limited humidity data for such runs indicate that the humidity was less than $5 \%$, probably no more than $\sim 2.5 \%$, and possibly much less than that. The default value corresponds to $\sim 2.5-3 \% \mathrm{RH}$ for the conditions of most experiments. |

[a] Set refers to the characterization set, which refers to the group of experiments assumed to have the same run conditions and represented using the same chamber-dependent parameters. See Carter et al (1995) for more discussion. All DTC experiments for the first phase of this program (DTC271-293) are in DTC characterization set 10 and those for the second phase (DTC299 and later) are in characterization set 11. All CTC experiments for the first phase of the program are in CTC characterization set 6 . For the CTC runs in the second phase, runs CTC155 through CTC168 are in set 7, and runs CTC230 to CTC247 were in set 9 .

[^0]:    ${ }^{1}$ Note that this differs from how the term "incremental reactivity" is used in the context of chamber experiments. In that case, the incremental reactivity refers to the relative change observed in the individual experiments, which in general depends on the amount added.
