#### Abstract

A series of environmental chamber experiments and computer model calculations were carried out to assess the atmospheric ozone formation potentials of methyl pivalate. The experiments consisted of determining the effects of this compound on NO oxidation, ozone formation, OH radical levels, and other measures of reactivity when added to varying simulated model photochemical smog systems. Methyl pivalate was found to slightly enhance $\mathrm{O}_{3}$ formation under conditions most representative of the atmosphere, but to inhibit radical levels and inhibit $\mathrm{O}_{3}$ in experiments that are sensitive to effects on radical levels. A mechanism for the atmospheric reaction for methyl pivalate was developed that is consistent with available laboratory data and current estimation methods, and that could simulate the results of these experiments after only minor adjustments of the overall nitrate yield to within its range of uncertainty. This mechanism was then incorporated in the overall SAPRC-99 mechanism and used to predict the atmospheric ozone impacts of this compound under various atmospheric conditions. The ozone formation potentials of methyl pivalate on a mass basis was found to be about $10-20 \%$ that of the mixture used to represent reactive VOC emissions from all sources. Its ozone formation potentials were found to be very similar to those of ethane, the compound used by the EPA as the basis for determining exemptions of compounds from regulation as ozone precursors.

## ACKNOWLEDGEMENTS

The authors acknowledge Mr. Dennis Fitz for assistance in administering this program, Mr. Kurt Bumiller with assistance in carrying out the environmental chamber experiments, and Dr. Roger Atkinson for helpful discussions.

Although this work was funded by ExxonMobil Chemical Company, the opinions and conclusions expressed in this report are entirely those of the primary author, Dr. William P. L. Carter. Mention of trade names or commercial products do not constitute endorsement or recommendation for use.

## INTRODUCTION

Ozone in photochemical smog is formed from the gas-phase reactions of volatile organic compounds (VOCs) and oxides of nitrogen $\left(\mathrm{NO}_{\mathrm{x}}\right)$ in sunlight. Although Houston and Los Angeles currently have the worst ozone problems in the United States, other areas of the country also have episodes where ozone exceeds the federal air quality standard. Ozone control strategies in the past have focused primarily on VOC controls, though the importance of $\mathrm{NO}_{\mathrm{x}}$ control has become recognized in recent years. VOC and $\mathrm{NO}_{\mathrm{x}}$ controls have differing effects on ozone formation. $\mathrm{NO}_{\mathrm{x}}$ is required for ozone formation, and if the levels of $\mathrm{NO}_{\mathrm{x}}$ are low compared to the levels of reactive VOCs, then changing VOC emissions will have relatively little effect on ozone. Since $\mathrm{NO}_{\mathrm{x}}$ is removed from the atmosphere more rapidly than VOCs, ozone in areas far downwind from the primary sources tend to be more $\mathrm{NO}_{\mathrm{x}}$ limited, and thus less responsive to VOC controls. VOC controls tend to reduce the rate that $\mathrm{O}_{3}$ is formed when $\mathrm{NO}_{\mathrm{x}}$ is present, so VOC controls are the most beneficial in reducing $\mathrm{O}_{3}$ in the urban source areas, where $\mathrm{NO}_{x}$ is relatively plentiful, and where $\mathrm{O}_{3}$ yields are determined primarily by how rapidly it is being formed. Because of this, any comprehensive ozone control strategy should involve reduction of emissions of both $\mathrm{NO}_{\mathrm{x}}$ and VOCs.

Many different types of VOCs are emitted into the atmosphere, each reacting at different rates and having different mechanisms for their reactions. Because of this, they can differ significantly in their effects on ozone formation, or their "reactivity". Some compounds, such as CFCs, do not react in the lower atmosphere at all, and thus make no contribution to ground-level ozone formation. Others, such as methane, react and contribute to ozone formation, but react so slowly that their practical effect on ozone formation in urban atmospheres is negligible. Obviously, it does not make sense to regulate such compounds as ozone precursors. In recognition of this, the EPA has exempted certain compounds from such regulations on the basis of having "negligible" effects on ozone formation. Although the EPA has no formal policy on what constitutes "negligible" reactivity, in practice it has used the ozone formation potential of ethane as the standard in this regard. Therefore, the ozone formation potential of a compound relative to ethane is of particular interest when assessing whether it might be a likely candidate for exemption from regulation as an ozone precursor.

Many VOCs that would not be judged to have "negligible" reactivity under the current criterion might still have much lower ozone formation potential than average, and substituting emissions of highly reactive VOCs with such moderate-to-low reactivity VOCs would be expected to result in air quality improvements. Although the current EPA policies do not encourage such substitutions, it has been proposed to implement reactivity-based policies on a voluntary basis in consumer product regulations in California (CARB, 1999), and the EPA is currently re-evaluating its reactivity-based VOC policies (Dimitriades, 1999, RRWG, 1999). Mc.Bride et al (1997) showed that adopting reactivity-based VOC control policies could result in significant cost savings in ozone reduction strategies, though a number of difficult policy and enforcement issues need to be resolved (RRWG, 1999). Although regulatory
approaches that appropriately deal with differences in VOC reactivity are still evolving, it is clear that producers of solvent VOCs will need to know how their VOCs might be classified under any such system, so they can appropriately adapt to reactivity-based policies once they are implemented. This requires an ability to reliably estimated the ozone impacts of the VOCs of interest.

Methyl pivalate, $\mathrm{CH}_{3} \mathrm{OC}(\mathrm{O}) \mathrm{C}\left(\mathrm{CH}_{3}\right)_{3}$, is a compound produced by ExxonMobil Chemical Company that has a potential market for many solvent applications. If this compound were to be shown to have sufficiently low ozone reactivity that it can be exempted from regulation as an ozone precursor, its market as a replacement solvent would be significantly enhanced. An initial modeling assessment suggested that this might be the case (Carter, unpublished results). Because of this Exxon Chemical Company (now ExxonMobil) contracted the College of Engineering Center for Environmental Research and Technology (CE-CERT) to carry out the experimental and modeling study needed to provide more definitive evidence in this regard. This involves conducting environmental chamber experiments to determine the effects of the compound on $\mathrm{O}_{3}$ formation and other measures of air quality under various conditions, and then using the results to determine if current estimated mechanisms for this compound can appropriately predict its atmospheric impact. Once its predictive capability is established, the mechanism can then be used in model calculations to determine its ozone impacts under various atmospheric conditions. The results can then be compared for the ozone impacts calculated for ethane under those same conditions, to determine if methyl pivalate has sufficiently low ozone impact under the standards currently used by the EPA to be exempted from regulation as an ozone precursor. The results of this study are documented in this report.

## EXPERIMENTAL AND DATA ANALYSIS METHODS

## Overall Experimental Approach

Most of the environmental chamber experiments for this program consisted of measurements of "incremental reactivities" of methyl pivalate under various conditions. These involve two types of irradiations of model photochemical smog mixtures. The first is a "base case" experiment where a mixture of reactive organic gases (ROGs) representing those present in polluted atmospheres (the "ROG surrogate") is irradiated in the presence of oxides of nitrogen $\left(\mathrm{NO}_{\mathrm{x}}\right)$ in air. The second is the "test" experiment that consists of repeating the base case irradiation except that the VOC whose reactivity is being assessed is also added. The differences between the results of these experiments provide a measure of the atmospheric impact of the test compound, and the difference relative to the amount added is a measure of its reactivity. To provide data concerning the reactivities of the test compound under varying atmospheric conditions, three types of base case experiments were carried out:

Mini-Surrogate Experiments. This base case employs a simplified ROG surrogate and relatively low ROG/ $\mathrm{NO}_{\mathrm{x}}$ ratios. Low $\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ ratios represent "maximum incremental reactivity" (MIR) conditions, which are most sensitive to VOC effects. This is useful because it provides a sensitive test for the model, and also because it is most important that the model correctly predict a VOC's reactivity under conditions where the atmosphere is most sensitive to the VOCs. The ROG mini-surrogate mixture employed consisted of ethene, n-hexane, and m-xylene. It consists of the following average initial concentrations (in ppm): NO: $0.30, \mathrm{NO}_{2}: 0.10$, n-hexane: 0.50 , ethene: 0.85 , and m-xylene: 0.14 . This surrogate was employed in our previous studies (Carter et al, 1993; 1995a-c, 1997, 2000a), and was found to provide a more sensitive test of the mechanism than the more complex surrogates that more closely represent atmospheric conditions (Carter et al, 1995b). This high sensitivity to mechanistic differences makes the mini-surrogate experiments most useful for mechanism evaluation.

Full Surrogate Experiments. This base case employed a more complex ROG surrogate under somewhat higher, though still relatively low, $\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ conditions. While less sensitive to the mechanism employed, experiments with a more representative ROG surrogate are needed to evaluate the mechanism under conditions that more closely resembling the atmosphere. The ROG surrogate employed was the same as the 8 -component "lumped molecule" surrogate employed in our previous study (Carter et al. 1995b. Calculations have indicated that use of this 8 -component mixture will give essentially the same results in incremental reactivity experiments as actual ambient mixtures (Carter et al. 1995b). It consists of the following average initial concentrations, in ppm: $\mathrm{NO}: 0.25, \mathrm{NO}_{2}: 0.05$, n-butane: 0.40 , n -octane: 0.10 , ethene: 0.07 , propene: 0.06 , trans-2-butene: 0.06 , toluene: 0.09 , m-xylene 0.09 , and formaldehyde: 0.10 .

Full Surrogate, low $\mathrm{NO}_{\underline{x}}$ Experiments. This base case employing the same 8 -component "lumped molecule" surrogate as the full surrogate experiments described above, except that lower $\mathrm{NO}_{\mathrm{x}}$ levels (higher
$\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ ratios) were employed to represent $\mathrm{NO}_{\mathrm{x}}$-limited conditions. Such experiments are necessary to assess the ability of the model to properly simulate reactivities under conditions where $\mathrm{NO}_{\mathrm{x}}$ is low. The initial ROG and $\mathrm{NO}_{x}$ reactant concentrations were comparable to those employed in our previous studies (Carter et al. 1995b, 1997, 2000a). The initial concentrations are the same as above except for 0.06 ppm of NO and 0.03 ppm of $\mathrm{NO}_{2}$.

An appropriate set of control and characterization experiments necessary for assuring data quality and characterizing the conditions of the runs for mechanism evaluation were also carried out. These are discussed where relevant in the results or modeling methods sections (see also Carter et al, 1995c, 2000a).

## Environmental Chamber

All experiments for this program were carried out using the CE-CERT "Dividable Teflon Chamber" (DTC) with a blacklight light source. This consists of two $\sim 6000$-liter 2-mil heat-sealed FEP Teflon reaction bags located adjacent to each other and fitted inside an $8^{\prime} \times 8^{\prime} \times 8^{\prime}$ framework, and which uses two diametrically opposed banks of 32 Sylvania 40-W BL black lights as the light source. The lighting system in the DTC was found to provide so much intensity that only half the lights were used for irradiation. The air conditioner for the chamber room was turned on before and during the experiments. Four air blowers that are located in the bottom of the chamber were used to help cool the chamber as well as mix the contents of the chamber. The CE-CERT DTC is very similar to the SAPRC DTC which is described in detail elsewhere (Carter et al, 1995b,c).

The blacklight light source has the advantage of being relatively inexpensive to operate and provides a reasonably good simulation of natural sunlight in the region of the spectrum that is important in affecting most photolysis reactions of importance for non-aromatic VOCs (Carter et al, 1995c,d). This is therefore appropriate for studies of reactivities of compounds, such as methyl pivalate, which are not photoreactive or believed to form significant yields of photoreactive products whose action spectra are not well characterized.

The DTC is designed to allow simultaneous irradiations of experiments with and without added test reactants under the same reaction conditions. Since the chambers are actually two adjacent FEP Teflon reaction bags, two mixtures can be simultaneously irradiated using the same light source and with the same temperature control system. These two reaction bags are referred to as the two "sides" of the chambers (Side A and Side B) in the subsequent discussion. The sides are interconnected with two ports, each with a box fan, which rapidly exchange their contents to assure that base case reactants have equal concentrations in both sides. In addition, a fan is located in each of the reaction bags to rapidly mix the reactants within each chamber. The ports connecting the two reactors can then be closed to allow separate injections on each side, and separate monitoring of each side.

## Experimental Procedures

The reaction bags were flushed with dry air produced by an AADCO air purification system for 14 hours ( $6 \mathrm{pm}-8 \mathrm{am}$ ) on the nights before experiments. The continuous monitors were connected prior to reactant injection and the data system began logging data from the continuous monitoring systems. The reactants were injected as described below (see also Carter et al, 1993, 1995c). The common reactants were injected in both sides simultaneously using a three-way (one inlet and two outlets connected to side A and B respectively) bulb of 2 liters in the injection line and were well mixed before the chamber was divided. The contents of each side were blown into the other using two box fans located between them. Fans were used to mix the reactants in the chamber during the injection period, but these were turned off prior to the irradiation. The sides were then separated by closing the ports that connected them, after turning all the fans off to allow their pressures to equalize. After that, reactants for specific sides (the test compound in the case of reactivity experiments) were injected and mixed. After the run, the contents of the chamber were emptied by allowing the bags to collapse, and then the chamber was flushed with purified air. The contents of the reactors were vented into a fume hood.

The procedures for injecting the various types of reactants were as follows. The NO and $\mathrm{NO}_{2}$ were prepared for injection using a high vacuum rack. Known pressures of NO, measured with MKS Baratron capacitance manometers, were expanded into Pyrex bulbs with known volumes, which were then filled with nitrogen (for NO ) or oxygen (for $\mathrm{NO}_{2}$ ). The contents of the bulbs were then flushed into the chamber with nitrogen. The gaseous reactants were prepared for injection either using a high vacuum rack or a gas-tight syringes whose amounts were calculated to achieve the desired concentrations in the chamber. Sufficiently volatile liquid reactants (which included methyl pivalate and liquid surrogate components used in this study) were injected using a micro syringe into a 1 -liter Pyrex bulb equipped with stopcocks on each end and a port for the injection of the liquid. Then one end of the bulb was attached to the injection port of the chamber and the other to a nitrogen source. The stopcocks were then opened, and the contents of the bulb were flushed into the chamber with a combination of nitrogen and heat gun for approximately 5 minutes. Formaldehyde was prepared in a vacuum rack system by heating paraformaldehyde in an evacuated bulb until the pressure corresponded to the desired amount of formaldehyde. The bulb was then closed and detached from the vacuum system and its contents were flushed into the chamber with dry air through the injection port.

## Analytical Methods

Ozone and nitrogen oxides $\left(\mathrm{NO}_{\mathrm{x}}\right)$ were continuously monitored using commercially available continuous analyzers with Teflon sample lines inserted directly into the chambers. The sampling lines from each side of the chamber were connected to solenoids that switched from side to side every 10 minutes, so the instruments alternately collected data from each side. Ozone was monitored using a Dasibi 1003-AH UV photometric ozone analyzer and NO and total oxides of nitrogen (including organic nitrates and perhaps $\mathrm{HNO}_{3}$ ) were monitored using a Teco Model 42 chemiluminescent $\mathrm{NO} / \mathrm{NO}_{x}$ monitor. The output of these instruments, along with that from the temperature sensors and the formaldehyde
instrument, were attached to a computer data acquisition system, which recorded the data at 10 minutes intervals for ozone, NOx and temperature (and at 15 minutes for formaldehyde), using 30 second averaging times. This yielded a sampling interval of 20 minutes for taking data from each side.

The Teco instrument and Dasibi CO analyzer were calibrated prior to each experiment using a certified NO and CO source and CSI 1700 gas-phase titration calibrator. The Dasibi ozone analyzer was calibrated against a transfer standard ozone analyzer using transfer standard method in an interval of three months and was checked with CSI ozone generator for each experiment to assure that the instrument worked properly. The details were discussed elsewhere (Carter et al, 1995c)

Organic reactants other than formaldehyde were measured by gas chromatography with FID detection as described elsewhere (Carter et al. 1993; 1995c). GC samples were taken for analysis at intervals from 20 minutes to 30 minutes either using 100 ml gas-tight glass syringes or by collecting the 100 ml sample from the chamber onto Tenax-GC solid adsorbent cartridge. These samples were taken from ports directly connected to the chamber after injection and before irradiation and at regular intervals after irradiation was started. The sampling method employed for injecting the sample onto the GC column depended on the volatility or "stickiness" of the compound. For analysis of the more volatile species, which includes methyl pivalate and all the other organic compounds monitored in this study, the contents of the syringe were flushed through a 10 ml and 5 ml stainless steel or $1 / 8^{\prime}$ Teflon tube loop and subsequently injected onto the column by turning a gas sample valve.

The calibrations for the GC analyses for most compounds were carried out by sampling from chambers or vessels of known volume into which known amounts of the reactants were injected, as described previously (Carter et al, 1995c).

Formaldehyde was monitored using an adaptation of the diffusion scrubber method developed by Dasgupta et al (1988, 1990), as described by Carter et al (1995c). It was calibrated using a formaldehyde diffusion tube whose weight loss was monitored over time. The system cycled between zero, calibrate, and sample modes to correct for zero and span drifts.

## Characterization Methods

## Temperature

Three temperature thermocouples were used to monitor the chamber temperature, two of which were located in the sampling line of continuous analyzers to monitor the temperature in each side. The third one was located in the outlet of the air conditioning system used to control the chamber temperature. The temperature range in these experiments was typically 25-30 C.

## Blacklight Light Source

The light intensity in the DTC chamber was monitored by periodic $\mathrm{NO}_{2}$ actinometry experiments utilizing the quartz tube method of Zafonte et al (1977), with the data analysis method modified as discussed by Carter et al. (1995c). The results of these experiments were tracked over time, and there was a gradual decrease in light intensity over time during most of the operational lifetime of this chamber. The actinometry results around the time of these experiments were fit reasonably well by a straight line up to run DTC704, and this was used to determine the $\mathrm{NO}_{2}$ photolysis rates used for modeling those runs. This line yielded an $\mathrm{NO}_{2}$ photolysis rate of $0.163 \mathrm{~min}^{-1}$ for DTC694, the first DTC run for this project, and $0.161 \mathrm{~min}^{-1}$ for run DTC704. For runs after DTC704 the results of the actinometry experiments did not indicate a significant decline in light intensity and $\mathrm{NO}_{2}$ photolysis rate used for modeling was the average of the experimental measurements for this period, which was $0.161 \mathrm{~min}^{-1}$.

The spectrum of the blacklight light source is periodically measured using a LiCor LI-1200 spectroradiometer, and found to be essentially the same as the general blacklight spectrum recommended by Carter et al (1995c) for use in modeling blacklight chamber experiments

## Dilution

The dilution of the chambers due to sampling is expected to be small because the flexible reaction bags can collapse as samples are withdrawn for analysis. Also, the chambers were designed to operate under slightly positive pressure, so any small leaks would result in reducing the bag volume rather than diluting the contents of the chamber. Information concerning dilution in an experiment can be obtained from relative rates of decay of added VOCs that react with OH radicals with differing rate constants (Carter et al. 1993; 1995c). Most experiments had a more reactive compound such as m-xylene and n-octane present either as a reactant or added in trace amounts to monitor OH radical levels. Trace amounts ( $\sim 0.1 \mathrm{ppm}$ ) of n -butane were also added to experiments if needed to provide a less reactive compound for monitoring dilution. In addition, specific dilution check experiments such as CO dark decay measurements were periodically carried out. Based on these results, the dilution rate was found to be negligible in this chamber during this period, being less than $0.3 \%$ per hour in all runs, and usually less than $0.1 \%$ per hour.

## Reactivity Data Analysis Methods

As indicated above, most of the experiments for this program consisted of simultaneous irradiation of a "base case" reactive organic gas (ROG) surrogate - $\mathrm{NO}_{x}$ mixture in one of the dual reaction chambers, together with an irradiation, in the other reactor, of the same mixture with the test compound added. The results are analyzed to yield two measures of VOC reactivity: the effect of the added VOC on the amount of NO reacted plus the amount of ozone formed, and integrated OH radical levels. These are discussed in more detail below.

The first measure of reactivity is the effect of the VOC on the change in the quantity $\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]$, or $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$. As discussed elsewhere (e.g., Johnson, 1983; Carter and Atkinson, 1987; Carter and Lurmann, 1990, 1991, Carter et al, 1993, 1995a), this gives a direct measure of the amount of conversion of NO to $\mathrm{NO}_{2}$ by peroxy radicals formed in the photooxidation reactions, which is the process that is directly responsible for ozone formation in the atmosphere. (Johnson calls it "smog produced" or "SP".) The incremental reactivity of the VOC relative to this quantity, which is calculated for each hour of the experiment, is given by

$$
\begin{equation*}
\operatorname{IR}\left[\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)_{\mathrm{t}}^{\mathrm{VoC}}\right]=\frac{\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)_{\mathrm{t}}^{\mathrm{Test}}-\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO})_{\mathrm{t}}^{\text {Base }}\right.}{[\mathrm{VOC}]_{0}} \tag{I}
\end{equation*}
$$

where $\Delta\left([\mathrm{O} 3]-[\mathrm{NO}]_{\mathrm{t}}{ }^{\text {Test }}\right.$ is the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ measured at time t from the experiment where the test VOC was added, $\Delta\left([\mathrm{O} 3]-[\mathrm{NO})_{\mathrm{t}}{ }^{\text {Base }}\right.$ is the corresponding value from the corresponding base case run, and $[\mathrm{VOC}]_{0}$ is the amount of test VOC added. An estimated uncertainty for $\operatorname{IR}\left[\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)\right]$ is derived based on assuming an $\sim 3 \%$ uncertainty or imprecision in the measured $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ values. This is consistent with the results of the side equivalency test, where equivalent base case mixtures are irradiated on each side of the chamber.

Note that reactivity relative to $\Delta([\mathrm{O} 3]-[\mathrm{NO}])$ is essentially the same as reactivity relative to $\mathrm{O}_{3}$ in experiments where $\mathrm{O}_{3}$ levels are high, because under such conditions $[\mathrm{NO}]_{t}^{\text {base }} .[\mathrm{NO}]_{t}^{\text {test }} .0$, so a change in $\Delta([\mathrm{O} 3]-[\mathrm{NO}])$ caused by the test compound is due to the change in $\mathrm{O}_{3}$ alone. However, $\Delta([\mathrm{O} 3]-[\mathrm{NO}])$ reactivity has the advantage that it provides a useful measure of the effect of the VOC on processes responsible for $\mathrm{O}_{3}$ formation even in experiments where $\mathrm{O}_{3}$ formation is suppressed by relatively high NO levels.

The second measure of reactivity is the effect of the VOC on integrated hydroxyl $(\mathrm{OH})$ radical concentrations in the experiment, which is abbreviated as "IntOH" in the subsequent discussion. This is an important factor affecting reactivity because radical levels affect how rapidly all VOCs present, including the base ROG components, react to form ozone. If a compound is present in the experiment that reacts primarily with OH radicals, then the IntOH at time t can be estimated from

$$
\begin{equation*}
\mathrm{IntOH}_{\mathrm{t}}=\frac{\ln \left([\text { tracer }]_{0} /[\text { tracer }]_{\mathrm{t}}\right)-\mathrm{Dt}}{\mathrm{kOH}^{\text {tracer }}} \tag{II}
\end{equation*}
$$

where $[\text { tracer }]_{0}$ and $[t r a c e r]_{t}$ are the initial and time $=t$ concentrations of the tracer compound, $\mathrm{kOH}^{\text {tracer }}$ its OH rate constant, and D is the dilution rate in the experiments. The latter was found to be small and was neglected in our analysis. The concentration of tracer at each hourly interval was determined by linear interpolation of the experimentally measured values. M-xylene was used as the OH tracer in these experiments because it is a surrogate component present in all experiments, its OH rate constant is known (the value used was $2.36 \times 10^{-11} \mathrm{~cm}^{3}$ molec $^{-1} \mathrm{~s}^{-1}$ [Atkinson, 1989]), and it reacts relatively rapidly.

The effect of the VOC on OH radicals can thus be measured by its IntOH incremental reactivity, which is defined as

$$
\begin{equation*}
\mathrm{IR}[\mathrm{IntOH}]_{\mathrm{t}}=\frac{\mathrm{IntOH}_{\mathrm{t}}^{\text {Test }}-\mathrm{IntOH}_{\mathrm{t}}^{\text {Base }}}{[\mathrm{VOC}]_{0}} \tag{III}
\end{equation*}
$$

where $\operatorname{IntOH}$ est and $\mathrm{IntOH}^{\text {Base }}$ are the IntOH values measured at time t in the added VOC and the base case experiment, respectively. The results are reported in units of $10^{6} \mathrm{~min}$. The uncertainties in IntOH and $\operatorname{IR}[\mathrm{IntOH}]$ are estimated based on assuming an $\sim 2 \%$ imprecision in the measurements of the m -xylene concentrations. This is consistent with the observed precision of results of replicate analyses of this compound.

# CHEMICAL MECHANISMS AND MODELING METHODS 

## Chemical Mechanism

## General Atmospheric Photooxidation Mechanism

The chemical mechanism used in the environmental chamber and atmospheric model simulations in this study is the SAPRC-99 mechanism that is documented in detail by Carter (2000). This mechanism represents a complete update of the SAPRC-90 mechanism of Carter (1990), and incorporates recent reactivity data from a wide variety of VOCs, including those discussed in this report. This includes assignments for $\sim 400$ types of VOCs, and can be used to estimate reactivities for $\sim 550$ VOC categories. A condensed version, developed for use in regional models, is used to represent base case emissions in the atmospheric reactivity simulations discussed in this report. A feature of this mechanism is the use of a computerized system to estimate and generate complete reaction schemes for most non-aromatic hydrocarbons and oxygenates in the presence of $\mathrm{NO}_{x}$, from which condensed mechanisms for the model can be derived. The SAPRC-99 mechanism was evaluated against the results of almost 1700 environmental chamber experiments carried out at the University of California at Riverside, including experiments to test ozone reactivity predictions for over 80 types of VOCs. This also includes experiments discussed in this report.

A listing of the mechanism as used in the model simulations in this report is given in Appendix A. This consists of the "base mechanism" representing the reactions of the inorganics and common organic products, the reactions of the specific VOCs used in the environmental chamber experiments, and the reactions of the lumped model species used when representing base case VOCs in the ambient reactivity simulations. The report of Carter (2000) should be consulted for a more detailed discussion of these portions of the mechanism. The mechanism used for methyl pivalate discussed below. Note that although the report of Carter (2000) included a mechanism for methyl pivalate, some minor modifications were made to the methyl pivalate mechanism used this work because of new data and other considerations.

## Atmospheric Reactions of Methyl Pivalate

The major gas-phase atmospheric loss process for methyl pivalate and other esters is expected to be reaction with OH radicals. Based on available information for related compounds, reaction of esters with $\mathrm{NO}_{3}$ radicals (Atkinson, 1991) and $\mathrm{O}_{3}$ (Atkinson and Carter, 1984; Atkinson, 1994) are expected to be unimportant. The possibility of photolysis can be ruled out on the basis of the absorption cross section data given by Calvert and Pitts (1977), and absorption cross section measurements made by Wallington et al (2000) for methyl pivalate.

The rate constant for the reaction of OH radicals with methyl pivalate has recently been measured by Orkin and co-workers (Wallington et al, 2000), and a non-Arrhenius temperature dependence was observed. The rate constants as a function of temperature were as follows:

where the error bars reflect the precision of the data and do not include an estimated systematic uncertainty of $4 \%$. The reason for this complex temperature dependence is uncertain, but it should be noted that a similar non-Arrhenius temperature dependence has been observed for the reaction of OH radicals with acetone (Wollenhaupt et al, 2000). Wallington et al (2000) attribute this to possible complex formation between the OH radical and the carbonyl group. In any case, the temperature variation in the 272330 K range is small (less than $3 \%$ variation between minimum and maximum), and for this work we ignore the small temperature dependence in the ambient temperature range and use the 298 K value of

$$
\mathrm{k}(\mathrm{OH}+\text { methyl pivalate })=1.18 \times 10^{-12} \mathrm{~cm}^{3} \mathrm{molec}^{-1} \mathrm{~s}^{-1} .
$$

No other measurements of this rate constant have been reported in the literature, though a qualitative measurement of $\sim 1.3 \times 10^{-12} \mathrm{~cm}^{3} \mathrm{molec}^{-1} \mathrm{~s}^{-1}$ made in our laboratory using a relative rate technique (unpublished results from our laboratory) is consistent with this. This is about $60 \%$ higher than the rate constant estimated using the group additivity methods of Kwok and Atkinson (1995), though this is within the uncertainty range of this estimation method.

The products of the reactions of OH radicals with methyl pivalate have recently been determined by Wallington et al (2000), who observed acetone formation in $51 \pm 6 \%$ yields. Methyl nitrite was used as the radical source, so the formaldehyde yield could not be determined because it is also formed from methyl nitrite. Essentially the same acetone yield ( $54 \pm 4 \%$ ) was observed in the reactions of Cl atoms with methyl pivalate in the presence of $\mathrm{NO}_{\mathrm{x}}$, where the mechanisms is expected to be similar. Formaldehyde, $\mathrm{CO}, \mathrm{CO}_{2}$, and $\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{OONO}_{2}$ were also observed to be formed in the product study of the Cl reaction in the presence of $\mathrm{NO}_{\mathrm{x}}$, but quantitative yields were not given. In addition, an upper limit of $7 \%$ was given for the formation of methyl pyruvate, $\mathrm{CH}_{3} \mathrm{C}(\mathrm{O}) \mathrm{C}(\mathrm{O}) \mathrm{OCH}_{3}$, and infrared bands corresponding to unidentified organic nitrate products were observed. Based on literature IR absorption cross sections for other organic nitrates, Wallington et al (2000) estimated an approximate $25 \%$ yield of unidentified organic nitrate products.

The expected mechanism for the reactions of OH radicals with methyl pivalate are shown on Table 1, which also gives the branching ratios and relative contributions of each reaction that are used as the basis for the mechanism derived for the model calculations in this work. Footnotes indicate the

Table 1. Detailed mechanism for the reactions of methyl pivalate with OH radicals in the presence of $\mathrm{NO}_{\mathrm{x}}$. Predicted products are shown in bold font.

Table 1 (continued)

| Reaction with OH [a] |  | Notes [b] | Branching [c] |  |

| $\mathrm{CH}_{3} \mathrm{C}\left(\mathrm{CH}_{3}\right)\left(\mathrm{CH}_{3}\right) \mathrm{C}(\mathrm{O}) \mathrm{OCH}_{2} \mathrm{O}$ - |  |  |  |  |
| 27 | $+\mathrm{O}_{2} \rightarrow \mathbf{C H}_{3} \mathbf{C}\left(\mathbf{C H}_{3}\right)\left(\mathbf{C H}_{3}\right) \mathbf{C}(\mathbf{O}) \mathbf{O C H O}+\mathrm{HO}_{2}$. |  | 3 | 34\% | 7\% |
| 28 | $\rightarrow \mathbf{C H}_{3} \mathbf{C}\left(\mathbf{C H}_{3}\right)\left(\mathbf{C H}_{3}\right) \mathbf{C}(\mathbf{O}) \mathbf{O H}+\mathrm{HCO}$. | 8 | 66\% | 14\% |

[a] Predicted stable organic products are shown in bold font.
[b] Documentation notes for branching ratios are as follows. See Carter (2000) for details concerning the estimation methods.
1 Branching ratio derived to give a predicted acetone yield that agrees with the measured yield of Wallington et al (unpublished results, 2000), as discussed in the text. This is not significantly different from the estimated $70 \%$ branching ratio derived using the group additivity method of Kwok and Atkinson (1995).
2 The branching ratio for nitrate formation (nitrate yield) is estimated to be $10 \%$ using the procedures of Carter (2000), based on yields derived for other compounds. However, best fits to the chamber data obtained in this project are obtained if the nitrate yields for the initially formed peroxy radicals are adjusted upwards to $13 \%$ (see text).
3 Rate constants for alkoxy radical reactions estimated as discussed by Carter (2000).
4 Nitrate yield for this reaction adjusted to fit environmental chamber reactivity data for methyl isobutyrate (Carter 2000; Carter et al, 2000a).
5 Assumed to react with the same rate constants as higher acyl peroxy radicals and PAN analogue (e.g., $\mathrm{C}_{2} \mathrm{H}_{4} \mathrm{C}(\mathrm{O}) \mathrm{OONO}_{2}$ and PPN ). Lumped with the RCO-O2. or PAN2 model species when implemented in the SAPRC-99 mechanism.
6 This decomposition is assumed to be fast.
7 Nitrate yield estimated from nitrate yields derived for other compounds as discussed by Carter (2000).

8 The data used by Carter (2000) to estimate rate constants for "ester rearrangement" reactions had an error, so the estimation method for these reactions is revised for this work. The rate constant for this ester rearrangement reaction is estimated to be $8.0 \times 10^{10} \exp \left(-8.49 \mathrm{kcal} \mathrm{mol}^{-1} / \mathrm{RT}\right)=5.24 \times 10^{4}$ $\mathrm{s}^{-1}$ at 300 K . The A factor assumed to be approximately the same as assumed for $1,4-\mathrm{H}$-shift isomerizations, based on expected similarities in transition states, and is the same as used by Carter (2000) The activation energies are assumed to be linearly dependent on the heat of reaction, where $\mathrm{Ea}=\mathrm{EaA}+\mathrm{EaB} \times \Delta \mathrm{H}_{\mathrm{r}}$, and $\mathrm{EaA}=9.11$ and $\mathrm{EaB}=0.20$ were derived to be consistent with $\mathrm{OH}+$ methyl acetate product yields reported by Christensen et al (2000), OH +ethyl acetate yields of Tuazon et al (1998), and results of modeling n-butyl acetate reactivity chamber experiments. Carter (2000) had an error in the assumed product yields for the $\mathrm{OH}+$ methyl acetate reaction, and thus the EaA and EaB parameters used there are somewhat different. The effect of this correction on estimated branching ratios for most compounds is minor, but is non-negligible for methyl pivalate.
[c] Predicted branching ratios. The "Rxn" column shows the importance of the reaction relative to the competing reactions of the species or radical. The "Total" column shows the importance of the reaction relative to the overall process.
[d] The relative importances of these reactions depend on $[\mathrm{NO}] /\left[\mathrm{NO}_{2}\right]$ ratio.
derivations of the branching ratios that are used. It can be seen that the predicted products, shown in bold font on the table, are consistent with the product data of Wallington et al (2000).

As indicated on Table 1, most branching ratios were estimated using the mechanism estimation procedures associated with the SAPRC-99 mechanism as documented by Carter (2000). Since the report of Carter (2000) describes these estimation procedures in detail, they are not discussed further here. However, as indicated on Footnote 8 on the table, Carter (2000) had a minor error in the estimates of ester rearrangement rate constants that affects estimates for compounds such as this, and that is corrected in this work. ${ }^{1}$ In addition, as also noted in the footnote, two adjustments were made to the estimated mechanism based on data obtained by Wallington et al (2000) and this work.

Model simulations of some of the environmental reactivity experiments are highly sensitive to the assumed nitrate yields in the reactions of peroxy radicals with NO (e.g., the ratios of rate constants for Reactions 4 and 5 and 25 and 26 on Table 1), and estimates of these rate constant ratios are highly uncertain (Carter, 2000). Therefore, for most compounds for which environmental chamber data are available and where the simulations are sensitive to these yields, the nitrate yields for the peroxy radicals formed in the initial reactions are generally adjusted to optimize the fits of model predictions to the data. As shown in the Results section, better fits to the data are obtained if nitrate yields in the reactions of NO with the initially formed peroxy radicals (i.e., Reactions 4 and 25) are assumed to be $\sim 13 \%$ instead of the initially estimated $\sim 10 \%$. This is well within the $\pm 60 \%$ uncertainty of the SAPRC- 99 nitrate yield estimation method.

The mechanism derived using the SAPRC-99 estimation procedures (Carter, 2000), corrected as indicated in Footnote 8, and with the nitrate yields adjusted as indicated above, predicts that the total acetone yield of $46 \%$. This is within the stated error limits of the $51 \pm 6 \%$ yield of Wallington et al (2000), and is in remarkably good agreement with these data given the number of uncertain rate constant estimates involved. This includes the estimate for the branching ratio for the initial OH reaction derived using the group additivity method of Kwok and Atkinson (1995). However, that estimate is clearly uncertain because this procedure gives a total rate constant that is low by $60 \%$. Therefore, it is not inappropriate to adjust that ratio slightly so the model prediction better matches the observed acetone yields. As indicated in Footnote 1 to Table 1, this is done by assuming that reaction at the t-butyl end is slightly faster than estimated using the group additivity methods, and occurs $75 \%$ of the time rather than $70 \%$ of the time. This gives an acetone yield of $\sim 50 \%$, corresponding to the data of Wallington et al (2000).

In terms of model species used in the SAPRC-99 mechanism (Carter, 2000), the overall process for the reactions shown on Table 3 can be represented as follows:

[^0]```
OH + Methyl Pivalate }->0.328\mathrm{ RO2-R. + 0.175 RO2-N. + 1.198 R2O2. + 0.497 RCO-O2. +
    0.194 CO + 0.619 HCHO + 0.034 RCHO + 0.497 ACET + 0.100 MEK + 0.194 RCO-OH
```

Here the RO2-R. represents the formation of peroxy radicals that react to convert NO to $\mathrm{NO}_{2}$ and form $\mathrm{HO}_{2}, \mathrm{RO} 2-\mathrm{N}$. represents the formation of peroxy radicals that react with NO to form organic nitrates, R2O2. represents extra NO to $\mathrm{NO}_{2}$ conversions caused by peroxy radicals formed in multi-step mechanisms, RCO-O2. represents the lumped higher acyl peroxy radical [used for $\mathrm{CH}_{3} \mathrm{OC}(\mathrm{O}) \mathrm{OO}$ - in this case], HCHO represents formaldehyde, RCHO represents the lumped higher aldehyde species [used for $\mathrm{CH}_{3} \mathrm{C}\left(\mathrm{CH}_{3}\right)(\mathrm{CHO}) \mathrm{C}(\mathrm{O}) \mathrm{OCH}_{3}$ ], ACET represents acetone, MEK represents the lumped lower reactivity oxygenated product (used for $\mathrm{CH}_{3} \mathrm{C}\left(\mathrm{CH}_{3}\right)\left(\mathrm{CH}_{3}\right) \mathrm{C}(\mathrm{O}) \mathrm{OCHO}$ and $\mathrm{CH}_{3} \mathrm{C}\left(\mathrm{CH}_{3}\right)(\mathrm{OH}) \mathrm{C}(\mathrm{O}) \mathrm{OCHO}$ ), and RCO-OH represents the lumped higher organic acid (used for $\mathrm{CH}_{3} \mathrm{C}\left(\mathrm{CH}_{3}\right)\left(\mathrm{CH}_{3}\right) \mathrm{C}(\mathrm{O}) \mathrm{OH}$ and $\left.\mathrm{CH}_{3} \mathrm{C}\left(\mathrm{CH}_{3}\right)(\mathrm{OH}) \mathrm{C}(\mathrm{O}) \mathrm{OH}\right)$.

## Modeling Methods

## Environmental Chamber Simulations

The ability of the chemical mechanisms to appropriately simulate the atmospheric impacts of methyl pivalate was evaluated by conducting model simulations of the environmental chamber experiments carried out for this study. This requires including in the model appropriate representations of chamber-dependent effects such as wall reactions and characteristics of the light source. The methods used are based on those discussed in detail by Carter and Lurmann (1990, 1991), updated as discussed by Carter et al. (1995c; 1997, 2000a). The photolysis rates were derived from results of $\mathrm{NO}_{2}$ actinometry experiments and measurements of the relative spectra of the light source. The thermal rate constants were calculated using the temperatures measured during the experiments, with the small variations in temperature with time during the experiment being taken into account. The computer programs and modeling methods employed are discussed in more detail elsewhere (Carter et al, 1995c). The specific values of the chamber-dependent parameters used in the model simulations of the experiments for this study are given in Table A-4 in Appendix A.

In the case of the methyl pivalate all model calculations used the mechanism discussed in the previous section, except for those showing the effects of using different overall methyl nitrate yields.

## Atmospheric Reactivity Simulations

To estimate its effect on ozone formation under conditions more representative of polluted urban atmospheres, incremental reactivities, defined as the change in $\mathrm{O}_{3}$ caused by adding small amounts of the compound to the emissions, were calculated for methyl pivalate, as well as for ethane and several other representative compounds. The scenarios employed are discussed in more detail later in this report, and are the same as used in our previous studies (Carter 1994a,b, 2000). The, software, and calculation
reactions forming this radical tend to be relatively unimportant except for the few relatively slowly reacting methyl esters such as methyl acetate and methyl pivalate.
procedures are as described by Carter (1994b), and were exactly the same as used by Carter (2000) when calculating the reactivity scale for the SAPRC-99 mechanism. The mechanism used is given in Appendix A.

## EXPERIMENTAL RESULTS AND MECHANISM EVALUATION

## Summary of Experiments and Characterization Results

Table 2 gives a chronological listing of all the experiments carried out for this program. These consisted primarily of the experiments with methyl pivalate, which are discussed in the next section. In addition to these, several characterization runs were carried out to determine the chamber-dependent inputs needed for the model simulations of the experiments. Table 2 summarizes the purposes and relevant results from these runs.

As indicated on Table 2, the results of most of these experiments were as expected based on our previous experience with these and similar chambers in our laboratories (Carter et al, 1995c and references therein; Carter et al, 2000a), and indicated no special problems with characterizing run conditions for mechanism evaluation. See Carter et al (2000a) for more discussion of the characterization results for these chambers during this time period, particularly with respect to light intensity and the chamber radical source. As noted on the table, some experiments were carried out following experiments where small amounts (usually less than 100 ppb ) of nitrous acid was injected into the chamber, and there was initially some concern that this might affect some experiments. However, no unusual results were found in characterization tests such as n-butane $-\mathrm{NO}_{\mathrm{x}}$ irradiations (which are sensitive to the chamber radical source) that followed such experiments.

A potentially more serious problem was a lack of side equivalency observed in the side equivalency test experiment DTC709 carried out around the end of this project. In this experiment, the same low $\mathrm{NO}_{\mathrm{x}}$ mini-surrogate mixture was irradiated on both sides of the chamber. As indicated in Table 2, somewhat less $\mathrm{O}_{3}$ was observed on Side B than Side A, and also the $\mathrm{O}_{3}$ decayed more rapidly on that side once the $\mathrm{O}_{3}$ maximum was reached. The $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ data and the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ differences between the two sides for that experiment are shown on Figure 1. To show the bias this might introduce on the experimentally $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ incremental reactivities, the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ differences between the two sides are also shown for the low $\mathrm{NO}_{\mathrm{x}}$ full surrogate runs where methyl pivalate was added. It can be seen that the bias introduced is relatively small for DTC702 but may be a non-negligible factor for run DTC700, where the amount of methyl pivalate added was smaller. However, except for the last two hours of the experiment, the side differences were within the error bars given for the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ incremental reactivity data. The relatively small side equivalency is not sufficient to affect the results in terms of whether the addition of methyl pivalate in these experiments enhances or inhibits $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ levels.

Figure 1 also shows the side differences in the IntOH data derived from the m -xylene consumption rate measurements in this side equivalency test run and also in the comparable runs with methyl pivalate added. In this case, the side equivalency appears to be reasonably good, with the IntOH changes being much less than in the added methyl pivalate runs, and within the estimated error limits.

Table 2. Chronological listing of the environmental chamber experiments carried out for this program.

| Run ID | Date | Title | Comments |
| :---: | :---: | :---: | :---: |
| DTC673 | 6/22/98 | $\mathrm{NO}_{2}$ Actinometry | $\mathrm{NO}_{2}$ photolysis rate measured using the quartz tube method was $0.156 \mathrm{~min}^{-1}$, in good agreement with the trend observed with the other such runs. |
| DTC682 | 7/8/98 | Ozone and CO dark Decay | Control run to check for leaks and measure the $\mathrm{O}_{3}$ wall decay rate. Essentially no CO decay was observed, indicating negligible leakage. The $\mathrm{O}_{3}$ decay rates were 1.4 x $10^{-4} \mathrm{~min}^{-1}$ on Side A and $1.6 \times 10^{-4} \mathrm{~min}^{-1}$ on Side B, in excellent agreement with the value of $1.5 \times 10^{-4} \mathrm{~min}^{-1}$ that is used when modeling these DTC runs. |
| DTC683 | 7/9/98 | Propene - $\mathrm{NO}_{\mathrm{x}}$ | Standard propene - $\mathrm{NO}_{\mathrm{x}}$ control run for comparison with other such runs in this and other chambers. Results in normal range. |
| DTC684 | 7/13/98 | $\mathrm{NO}_{2}$ Actinometry | $\mathrm{NO}_{2}$ photolysis rate measured using the quartz tube method was $0.160 \mathrm{~min}^{-1}$, in good agreement with the trend observed with the other such runs. |
|  | $\begin{gathered} 7 / 20- \\ 7 / 31 / 98 \end{gathered}$ | Runs for another program | Runs were carried out for other programs that involved injections of sub-ppm amounts of HONO in the chamber. Tests carried out in separate experiments indicate that this shouldn't affect the results of subsequent experiments. |
|  | $\begin{gathered} 8 / 4- \\ 8 / 7 / 98 \end{gathered}$ | Runs for another program |  |
| DTC694 | 8/12/98 | Mini-Surrogate + Methyl Pivalate | Mini-surrogate reactivity experiment with 11 ppm methyl pivalate added to Side A. Results on Table 3 and Figure 2. |
| DTC695 | 8/13/98 | Full Surrogate + Methyl Pivalate | High $\mathrm{NO}_{x}$ full surrogate reactivity experiment with 12 ppm methyl pivalate added to Side B. Results on Table 3 and Figure 2. |
|  | $\begin{gathered} 8 / 14- \\ 8 / 19 / 98 \end{gathered}$ | Runs for other program | A run was carried out for another programs that involved injections of sub-ppm amounts of HONO in the chamber., following reactivity experiments for other programs. |
| DTC699 | 8/20/98 | n-Butane - $\mathrm{NO}_{\mathrm{x}}$ | Characterization run to measure the chamber radical source. The NO oxidation rates were consistent with those predicted by the standard chamber model, but the rate on Side B was slightly higher than that on Side A. |
| DTC700 | 8/21/98 | Low $\mathrm{NO}_{\mathrm{x}}$ Full <br> Surrogate + Methyl <br> Pivalate (A) | Low $\mathrm{NO}_{\mathrm{x}}$ full surrogate reactivity experiment with 19 ppm methyl pivalate added to Side A. Results on Table 3 and Figure 2. |
| DTC701 | 8/26/98 | Mini-Surrogate + Methyl Pivalate | Mini-surrogate reactivity experiment with 16 ppm methyl pivalate added to Side B. Results on Table 3 and Figure 2. |
| DTC702 | 8/27/98 | Full Surrogate + Methyl Pivalate | High $\mathrm{NO}_{x}$ full surrogate reactivity experiment with 19 ppm methyl pivalate added to Side A. Results on Table 3 and Figure 2. |
|  | 8/28/98 | Runs for another program |  |

Table 2 (continued)

| Run ID | Date | Title | Comments |
| :---: | :---: | :---: | :---: |
| DTC704 | 8/31/98 | $\mathrm{NO}_{2}$ Actinometry | $\mathrm{NO}_{2}$ photolysis rate measured using the quartz tube method was $0.165 \mathrm{~min}^{-1}$, in good agreement with the trend observed with the other such runs. |
|  | 9/1/98 | Run for another program |  |
| DTC706 | 9/2/98 | Propene - $\mathrm{NO}_{\mathrm{x}}$ | Standard propene - $\mathrm{NO}_{\mathrm{x}}$ control run for comparison with other such runs in this and other chambers. Results in normal range. |
| DTC707 | 9/3/98 | Low $\mathrm{NO}_{\mathrm{x}}$ Full <br> Surrogate + Methyl <br> Pivalate | Low $\mathrm{NO}_{\mathrm{x}}$ full surrogate reactivity experiment with 29 ppm methyl pivalate added to Side B. Results on Table 3 and Figure 2. |
| DTC708 | 9/4/98 | Low $\mathrm{NO}_{\mathrm{x}}$ Full Surrogate Side equivalence Test | Irradiation of the same low $\mathrm{NO}_{x}$ full surrogate mixture was carried out in both reactors to determine side equivalency for this type of experiment. The NO oxidation rates and initial $\mathrm{O}_{3}$ formation rates were the same on both sides, but the maximum ozone was slightly less on Side B , and the $\mathrm{O}_{3}$ decayed slightly faster on that side once the peak $\mathrm{O}_{3}$ concentration was reached. The maximum and final $\mathrm{O}_{3}$ on side A was around 265 ppb , and the maximum $\mathrm{O}_{3}$ on side B was around 250 ppb after 3 hours, declining to $\sim 230 \mathrm{ppb}$ at the end of the 6 -hour run. N -Butane data suggest a slightly higher than normal leak rate on Side B, but it was still less than $1 \%$ per hour. |
| DTC709 | 9/8/98 | Ozone and CO dark Decay | Control run to check for leaks and measure the $\mathrm{O}_{3}$ wall decay rate just before replacing the reaction bag. Essentially no CO decay was observed, indicating negligible leakage. The $\mathrm{O}_{3}$ decay rates were $1.2 \times 10^{-4} \mathrm{~min}^{-1}$ on Side A and 2.1 $\times 10^{-4} \mathrm{~min}^{-1}$ in Side B, in fair agreement with the value of $1.5 \times 10^{-4} \mathrm{~min}^{-1}$ that is used when modeling these DTC runs. The higher decay rate in Side B is consistent with the results of run DTC708. However, changing the $\mathrm{O}_{3}$ wall loss rate within this range does not significantly affect results of model simulations of this run. |
| DTC710 | 10/19/98 | n-Butane - $\mathrm{NO}_{\mathrm{x}}$ | Run to measure the rate of the chamber radical source, as discussed by Carter et al (1995c). Results are well simulated using the standard chamber model assigned to this series of experiments, and good side equivalency was obtained. |
| DTC736 | 11/30/98 | $\mathrm{NO}_{2}$ Actinometry | $\mathrm{NO}_{2}$ photolysis rate measured using the quartz tube method was $0.162 \mathrm{~min}^{-1}$, suggesting that the light intensity is becoming approximately constant during this period. |

Figure 1. Selected results of the low $\mathrm{NO}_{\mathrm{x}}$ mini-surrogate side equivalency test experiment, and comparison with comparable data obtained in low $\mathrm{NO}_{\mathrm{x}}$ mini-surrogate experiments with added methyl pivalate.

[a] IR $=$ Incremental Reactivity $=([$ Test $]-[$ Base $]) /[$ Methyl Pivalate $]$

## Methyl Pivalate Reactivity Experiments

Six incremental reactivity experiments were carried out with methyl pivalate, two for each of the three types of base mixtures. The results are summarized on Table 3 and concentration-time plots of the major reactivity results are shown on Figure 2. Results of model calculations are also shown in the figure.

The results show that the effects of methyl pivalate on NO oxidation and $\mathrm{O}_{3}$ formation rates depend on the conditions of the experiments. It has a significant inhibiting effect on $\Delta([\mathrm{O} 3]-[\mathrm{NO}])$ in the mini-surrogate experiments and to a lesser extent inhibits it during the initial periods of the low $\mathrm{NO}_{\mathrm{x}}$ full surrogate runs. On the other hand it has relatively small but positive effects on $\mathrm{O}_{3}$ throughout most of the higher $\mathrm{NO}_{\mathrm{x}}$ full surrogate runs and the latter periods of the low $\mathrm{NO}_{\mathrm{x}}$ full surrogate experiments. It inhibits OH radical levels under all conditions, with the effects of this radical inhibition increasing during the course of the experiments. The magnitudes of the incremental reactivities are relatively low because of the relatively low OH radical rate constant for this compound.

The radical inhibition effects of methyl pivalate addition can be attributed to radical termination by the reactions of the peroxy radicals with NO forming organic nitrate and also to radical termination caused by the formation of the PAN analogue $\mathrm{CH}_{3} \mathrm{OC}(\mathrm{O}) \mathrm{OONO}_{2}$. Note that the relative importance of nitrate formation in terms of the total methyl pivalate oxidation process is independent of reaction conditions as long as sufficient $\mathrm{NO}_{\mathrm{x}}$ is present in the system that reaction with NO is the dominant loss process for peroxy radicals, while the relative importance of PAN analogue formation depends on the $\left[\mathrm{NO}_{2}\right] /[\mathrm{NO}]$ ratio which depends on reaction conditions.

The fact methyl pivalate inhibits $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ in the mini-surrogate runs while having positive effects on $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ during most periods in the full surrogate experiments is fairly common for VOCs with sufficiently large radical sinks in their mechanism. It is attributed to the fact that mini-surrogate experiments tend to be more sensitive to aspects of the mechanism concerning radical initiation and termination, while the full surrogate runs are relatively more sensitive to the positive effects of NO to $\mathrm{NO}_{2}$ conversions caused by the peroxy radicals formed when the VOC reacts. The latter stages of the low $\mathrm{NO}_{\mathrm{x}}$ full surrogate runs are also sensitive to $\mathrm{NO}_{\mathrm{x}}$ sinks in the VOC's mechanism, which if sufficiently large would cause negative ozone reactivities under those conditions. Apparently in the case of methyl pivalate the radical sinks are not sufficient to overcome the positive effects of the direct NO to $\mathrm{NO}_{2}$ conversions in under most conditions in the full surrogate runs. Similarly, the $\mathrm{NO}_{\mathrm{x}}$ sink caused by the formation of the PAN analogue is also not sufficient to overcome the positive effect of the NO to $\mathrm{NO}_{2}$ conversions in the low $\mathrm{NO}_{\mathrm{x}}$ full surrogate runs.

Consistent with the predicted and observed products in the reactions of OH with methyl pivalate, the addition of methyl pivalate in the reactivity experiments causes the formation of acetone (which is not formed in the base case experiments), and an increase in the formaldehyde levels in the full surrogate experiments. On the other hand, the methyl pivalate reduces the rate of formaldehyde formation in the mini-surrogate runs. This is attributed to the inhibiting effect of methyl pivalate on radical levels, which

Figure 2. Selected experimental and calculated results of the incremental reactivity experiments with methyl pivalate. (Effects of nitrate yield variation are not shown for simulated formaldehyde and acetaldehyde data.)
would reduce the rate of formaldehyde formation from ethylene, a major component of the minisurrogate. In the case of the mini-surrogate experiments this effect is enough to offset the formaldehyde formed from methyl pivalate's direct reactions. In the case of the full surrogate runs, the effects on overall radical levels are relatively less important, and also the formaldehyde formation from the base case
surrogate components is relatively less important compared to the initial formaldehyde and the formaldehyde formed from the added methyl pivalate.

The results of model simulations using the methyl pivalate mechanism discussed in the previous section are also shown on Figure 2. Three sets of calculations are shown, one (lines with darker, shorter dashes) using the alkyl nitrate yields derived using the SAPRC-99 estimation methods, one (lines with lighter longer dashes) using the $\sim 25 \%$ yield as estimated from the nitrate IR bands in the product study of Wallington et al (2000), and one (solid lines) using the nitrate yields judged to give the best overall fits to the data. The figure shows that the nitrate yields as derived using the SAPRC-99 estimation methods has a consistent bias towards underpredicting the inhibition or overpredicting the positive effects of methyl pivalate on $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$. This is removed by the relatively minor adjustment of increasing the nitrate yields from the initially formed radicals from $10 \%$ to $13 \%$. Although using the high $\sim 25 \%$ overall nitrate yield suggested by the data of Wallington et al (2000) gives better fits to the results of run DTC701, the results of the other experiments are poorly simulated with this model. Given the uncertainties in making quantitative yield estimates from IR bands without authentic calibration standards, the overall nitrate yields found to give the best fits to the data in this work are probably not outside uncertainty range of the yields derived by Wallington et al (2000).

The mechanism with the adjusted nitrate yields gives reasonably good simulations of the results of the reactivity experiments in this work. The one exception is run DTC701 where the inhibition of $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ is somewhat underestimated. However, the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ in the base case experiment for that run is also underpredicted by the model (the results of mini-surrogate experiments tend to be more sensitive to the variable chamber radical source), and this may bias the simulation of the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ reactivities. Overall the model gives a good prediction of how the $\Delta\left(\left[\mathrm{O}_{3}\right]-[\mathrm{NO}]\right)$ reactivities of methyl pivalate are affected by changes in chemical conditions.

The mechanism also gives reasonably good simulations of the effects of methyl pivalate on formaldehyde and acetone yields, and correctly predicts that it suppresses formaldehyde in the minisurrogate runs while enhancing it in the other experiments. It appears to have a bias towards underpredicting the yields of these compounds, though this may not be outside of experimental uncertainty. Note that the amount of methyl pivalate that reacts could not be experimentally determined because the fraction reacted is relatively low, and if the model is underestimating the amount of methyl pivalate reacting it would underestimate the yields of its products.

The mechanism gives good predictions of the IntOH reactivities of methyl pivalate, except for the low $\mathrm{NO}_{\mathrm{x}}$ full surrogate runs where the inhibition of IntOH reactivity is underpredicted. However, the inhibitions of IntOH reactivities in low $\mathrm{NO}_{\mathrm{x}}$ full surrogate runs are underpredicted for almost all VOCs, even compounds with relatively simple mechanisms such as CO (Carter et al, 1995a, 2000). Thus this is more likely due to a problem of the mechanism in simulating the conditions of the base case experiment under low $\mathrm{NO}_{\mathrm{x}}$ conditions than necessarily a problem with the VOC whose reactivity is being tested.

## ATMOSPHERIC REACTIVITY CALCULATIONS

Incremental reactivities of VOCs have been shown to be highly dependent on environmental conditions, so reactivities measured in environmental chamber experiments cannot necessarily be assumed to be the same as those under atmospheric conditions (Carter and Atkinson, 1989; Carter et al, 1995b). Because of this, the only method available to obtain quantitative estimates of incremental reactivities of VOCs in ambient air pollution episodes is to conduct airshed model simulations of the episodes. Since these simulations cannot be any more reliable than the chemical mechanisms used, the major objective of this program was to assess the reliability of the methyl pivalate mechanism for use in such calculations. As discussed above, the results of the experiments indicate that the mechanism developed in this work serves as an appropriate basis for estimating the effects of this compound on ozone under atmospheric conditions. The atmospheric reactivity estimates based on this mechanism are discussed in this section.

Note that Carter (2000) already gives reactivity estimates for the methyl pivalate, calculated using the same (SAPRC-99) mechanism. However, some updates were made to the methyl pivalate mechanism in the process of preparing this report that were not incorporated in the mechanism used by Carter (2000), so the reactivities calculated for this compound will be slightly different. The effect of this change is relatively minor, as can be seen in the results presented below.

## Scenarios Used for Reactivity Assessment

The set of airshed scenarios employed to assess the reactivities for this study is the same as those used for calculating the MIR and other reactivity scales in our previous work (Carter, 1994a), and also in the update using the SAPRC-99 mechanism (Carter, 2000). These scenarios, and the reasons for using them, are briefly described below.

The objective is to use a set of scenarios that represents, as much as possible, a comprehensive distribution of the environmental conditions where unacceptable levels of ozone are formed. Although a set of scenarios has not been developed for the specific purpose of VOC reactivity assessment, the EPA developed an extensive set of scenarios for conducting analyses of effects of ROG and $\mathrm{NO}_{\mathrm{x}}$ controls on ozone formation using the EKMA modeling approach (Gipson et al. 1981; Gipson and Freas, 1983; EPA, 1984; Gery et al. 1987; Baugues, 1990). The EKMA approach involves the use of single-cell box models to simulate how the ozone formation in one day episodes is affected by changes in ROG and $\mathrm{NO}_{\mathrm{x}}$ inputs. Although single-cell models cannot represent realistic pollution episodes in great detail, they can represent dynamic injection of pollutants, time-varying changes of inversion heights, entrainment of pollutants from aloft as the inversion height rises, and time-varying photolysis rates, temperatures, and humidities (Gipson and Freas, 1981; EPA, 1984; Gipson, 1984; Hogo and Gery, 1988). Thus, they can be used to simulate a wide range of the chemical conditions which affect ozone formation from ROG and $\mathrm{NO}_{x}$, and which affect VOC reactivity. Therefore, at least to the extent they are suitable for their intended
purpose, an appropriate set of EKMA scenarios should also be suitable for assessing reactivities over a wide range of conditions.

## Base Case Scenarios

The set of EKMA scenarios used in this study were developed by the United States EPA for assessing how various ROG and $\mathrm{NO}_{\mathrm{x}}$ control strategies would affect ozone nonattainment in various areas of the country (Baugues, 1990). The characteristics of these scenarios and the methods used to derive their input data are described in more detail elsewhere (Baugues, 1990; Carter, 1994b). Briefly, 39 urban areas in the United States were selected based on geographical representativeness of ozone nonattainment areas and data availability, and a representative high ozone episode was selected for each. The initial nonmethane organic carbon (NMOC) and $\mathrm{NO}_{\mathrm{x}}$ concentrations, the aloft $\mathrm{O}_{3}$ concentrations, and the mixing height inputs were based on measurement data for the various areas, the hourly emissions in the scenarios were obtained from the National Acid Precipitation Assessment Program emissions inventory (Baugues, 1990), and biogenic emissions were also included. Table 4 gives a summary of the urban areas represented and other selected characteristics of the scenarios.

Several changes to the scenario inputs were made based on discussions with the California ARB staff and others (Carter, 1994a,b). Two percent of the initial $\mathrm{NO}_{\mathrm{x}}$ and $0.1 \%$ of the emitted $\mathrm{NO}_{\mathrm{x}}$ in all the scenarios was assumed to be in the form of HONO. The photolysis rates were calculated using solar light intensities and spectra calculated by Jeffries (1991) for 640 meters, the approximate mid-point of the mixed layer during daylight hours. The composition of the non methane organic pollutants entrained from aloft was based on the analysis of Jeffries et al. (1989). The composition of the initial and emitted reactive organics was derived as discussed below. Complete listings of the input data for the scenarios are given elsewhere (Carter, 1994b).

This set of 39 EKMA scenarios are referred to as "base case" to distinguish them from the scenarios derived from them by adjusting $\mathrm{NO}_{\mathrm{x}}$ inputs to yield standard conditions of $\mathrm{NO}_{\mathrm{x}}$ availability as discussed below. No claim is made as to the accuracy of these scenarios in representing any real episode, but they are a result of an effort to represent, as accurately as possible given the available data and the limitations of the formulation of the EKMA model, the range of conditions occurring in urban areas throughout the United States. When developing general reactivity scales it is more important that the scenarios employed represent a realistic distribution of chemical conditions than accurately representing the details of any one particular episode.

The Base ROG mixture is the mixture of reactive organic gases used to represent the chemical composition of the initial and emitted anthropogenic reactive organic gases from all sources in the scenarios. Consistent with the approach used in the original EPA scenarios, the same mixture was used for all scenarios. The speciation for this mixture was derived by Croes (1991) based on an analysis of the EPA database (Jeffries et al. 1989) for the hydrocarbons and the 1987 Southern California Air Quality

Study (SCAQS) database for the oxygenates (Croes et al. 1994; Lurmann and Main. 1992). This mixture consists of $52 \%$ (by carbon) alkanes, $15 \%$ alkenes, $27 \%$ aromatics, $1 \%$ formaldehyde, $2 \%$ higher aldehydes, $1 \%$ ketones, and $2 \%$ acetylene. The detailed composition of this mixture is given elsewhere (Carter, 1994b; Carter, 2000).

## Adjusted $\mathbf{N O}_{\mathbf{x}}$ scenarios

Incremental reactivities in the base case scenarios would be expected to vary widely, since incremental reactivities depend on the $\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ ratio, and that ratio varies widely among the base case scenarios. To obtain reactivity scales for specified $\mathrm{NO}_{\mathrm{x}}$ conditions, separate scenarios, designated MIR (for maximum incremental reactivity), MOIR (for maximum ozone incremental reactivity), and Equal Benefit Incremental Reactivity (EBIR) were developed (Carter, 1994a). In the MIR scenarios, the $\mathrm{NO}_{\mathrm{x}}$ inputs were adjusted so the base ROG mixture (and most other VOCs) has its highest incremental reactivity. This is representative of the highest $\mathrm{NO}_{\mathrm{x}}$ conditions of relevance to VOC reactivity assessment because at higher $\mathrm{NO}_{x}$ levels $\mathrm{O}_{3}$ yields become significantly suppressed, but is also the condition where $\mathrm{O}_{3}$ is most sensitive to VOC emissions. In the MOIR scenarios, the $\mathrm{NO}_{\mathrm{x}}$ inputs were adjusted to yield the highest ozone concentration. In the EBIR scenarios, the $\mathrm{NO}_{x}$ inputs were adjusted so that the relative effects of $\mathrm{NO}_{\mathrm{x}}$ reductions and total ROG reductions on peak ozone levels were equal. This represents the lowest $\mathrm{NO}_{\mathrm{x}}$ condition of relevance for VOC reactivity assessment, because $\mathrm{O}_{3}$ formation becomes more sensitive to $\mathrm{NO}_{\mathrm{x}}$ emissions than VOC emissions at lower $\mathrm{NO}_{\mathrm{x}}$ levels. As discussed by Carter (1994a) the MIR and EBIR ROG/ $\mathrm{NO}_{\mathrm{x}}$ ratios are respectively $\sim 1.5$ and $\sim 0.7$ times those for the MOIR scenarios in all cases.

## $\mathrm{NO}_{\mathbf{x}}$ Conditions in the Base Case Scenarios

The variability of ROG/ $\mathrm{NO}_{\mathrm{x}}$ ratios in the base case scenarios suggests a variability of reactivity characteristics in those scenarios. However, as discussed previously (Carter, 1994a), the $\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ ratio is also variable in the MIR or MOIR scenarios, despite the fact that the $\mathrm{NO}_{\mathrm{x}}$ inputs in these scenarios are adjusted to yield a specified reactivity characteristic. Thus, the $\mathrm{ROG} / \mathrm{NO}_{\mathrm{x}}$ ratio, by itself, is not necessarily a good predictor of reactivity characteristics of a particular scenario. The $\mathrm{NO}_{\mathrm{x}} / \mathrm{NO}_{\mathrm{x}}{ }^{\text {MOIR }}$ ratio is a much better predictor of this, with values greater than 1 indicating relatively high $\mathrm{NO}_{x}$ conditions where ozone formation is more sensitive to VOCs, and values less than 1 indicating $\mathrm{NO}_{\mathrm{x}}$-limited conditions. $\mathrm{NO}_{\mathrm{x}} / \mathrm{NO}_{\mathrm{x}}{ }^{\text {MOIR }}$ ratios less than 0.7 represent conditions where $\mathrm{NO}_{\mathrm{x}}$ control is a more effective ozone control strategy than ROG control (Carter, 1994a). Note that more than half of the base case scenarios represent $\mathrm{NO}_{\mathrm{x}}$-limited conditions, and $\sim 25 \%$ of them represent conditions where $\mathrm{NO}_{\mathrm{x}}$ control is more beneficial than VOC control. A relatively small number of scenarios represent MIR or near MIR conditions. However, as discussed elsewhere (Carter, 1994a), this set of scenarios is based on near-worstcase conditions for ozone formation in each of the airsheds. Had scenarios representing less-than-worstcase conditions been included, one might expect a larger number of MIR or near MIR scenarios. This is because $\mathrm{NO}_{\mathrm{x}}$ is consumed more slowly on days with lower light intensity or temperature, and thus the scenario is less likely to become $\mathrm{NO}_{x}$-limited.

## Quantification of Atmospheric Reactivity

The reactivity of a VOC in an airshed scenario is measured by its incremental reactivity. For ambient scenarios, this is defined as the change in ozone caused by adding the VOC to the emissions, divided by the amount of VOC added, calculated for sufficiently small amounts of added VOC that the incremental reactivity is independent of the amount added ${ }^{2}$.

$$
\begin{equation*}
\mathrm{IR}(\text { VOC,Scenario })=\lim _{V O C \rightarrow 0}\left[\frac{\mathrm{O}_{3}(\text { Scenario with VOC })-\mathrm{O}_{3}(\text { Base Scenario })}{\text { Amount of VOC Added }}\right] \tag{IV}
\end{equation*}
$$

The specific calculation procedure is discussed in detail elsewhere (Carter, 1994a,b).
Incremental reactivities derived as given above tend to vary from scenario to scenario because they differ in their overall sensitivity of $\mathrm{O}_{3}$ formation to VOCs. These differences can be factored out to some extent by using "relative reactivities", which are defined as ratios of incremental reactivities to the incremental reactivity of the base ROG mixture, which is used to represent emissions of reactive VOCs from all sources.

$$
\begin{equation*}
\mathrm{RR}(\text { VOC,Scenario })=\frac{\mathrm{IR}(\text { VOC, Scenario })}{\operatorname{IR}(\text { Base ROG, Scenario })} \tag{V}
\end{equation*}
$$

These relative reactivities can also be thought of as the relative effect on $\mathrm{O}_{3}$ of controlling emissions of the particular VOC by itself, compared to controlling emissions from all VOC sources equally. Thus, they are more meaningful in terms of control strategy assessment than absolute reactivities, which can vary greatly depending on the episode and local meteorology.

In addition to depending on the VOC and the scenario, the incremental and relative reactivities depend on how the amounts of VOC added are quantified. In this work, this is quantified on a mass basis, since this is how VOCs are regulated, and generally approximates how VOC substitutions are made in practice. Note that relative reactivities will be different if they are quantified on a molar basis, with VOCs with higher molecular weight having higher reactivities on a mole basis than a gram basis.

Relative reactivities can also depend significantly on how ozone impacts are quantified (Carter, 1994a). Two different ozone quantification methods are used in this work, as follows:
"Ozone Yield" reactivities measure the effect of the VOC on the total amount of ozone formed in the scenario at the time of its maximum concentration. Incremental reactivities are quantified as grams $\mathrm{O}_{3}$ formed per gram VOC added. Most previous recent studies of ozone reactivity (Dodge, 1984; Carter and

[^1]Atkinson, 1987, 1989, Chang and Rudy, 1990; Jeffries and Crouse, 1991) have been based on this quantification method. The MIR, MOIR, and EBIR scales of Carter (1994a) also use this quantification.
"Maximum 8 Hour Average" reactivities measure the effect of the VOC on the average ozone concentration during the 8 -hour period when the average ozone concentration was the greatest, which in these one-day scenarios was the last 8 hours of the simulation. This provides a measure of ozone impact that is more closely related to the new Federal ozone standard that is given in terms of an 8 hour average. This quantification is used for relative reactivities in this work.

In previous reports, we have reported reactivities in terms of integrated $\mathrm{O}_{3}$ over a standard concentration of 0.09 or 0.12 ppm . This provides a measure of the effect of the VOC on exposure to unacceptable levels of ozone. This is replaced by the maximum 8 hour average reactivities because it is more representative of the proposed new Federal ozone standard and because reactivities relative to integrated $\mathrm{O}_{3}$ over a standard tend to be between those relative to ozone yield and those relative to 8 -hour averages. Therefore, presenting both ozone yield and maximum 8 -hour average relative reactivities should be sufficient to provide information on how relative reactivities vary with ozone quantification method. Incremental reactivities are quantified as $\mathrm{ppm}_{3}$ per milligram VOC emitted per square meter, but maximum 8 hour average reactivities are usually quantified as relative reactivities quantified on a mass basis.

Note that incremental reactivities are calculated for a total of 156 scenarios, consisting of the 39 base case scenarios and the three adjusted $\mathrm{NO}_{\mathrm{x}}$ scenarios for each of the 39 base case scenarios. However, the incremental reactivities in the MIR, MOIR, or EBIR) scales are reported as averages of the incremental reactivities in the corresponding adjusted $\mathrm{NO}_{\mathrm{x}}$ scenarios, because adjusting the $\mathrm{NO}_{\mathrm{x}}$ conditions reduces the scenario variability, and this allows for a derivation single reactivity scales representing each type of $\mathrm{NO}_{\mathrm{x}}$ condition. On the other hand, the individual scenario results will be shown for the base case scenarios, to give an indication of the scenario-to-scenario variability of the calculated reactivity results.

## Results

Table 5 lists the ozone yield incremental reactivities calculated for methyl pivalate, ethane, acetone and the mixture of emitted reactive organic compounds (the base ROG). The methyl pivalate reactivity results shown are those calculated using the mechanism developed in this work that gave the best fits to the chamber that, and also those as given by Carter (2000) ("SAPRC-99"), which as indicated above was slightly revised in this work. Table 6 gives the ozone yield and maximum 8 -hour average reactivities relative to the base ROG for three compounds. Ethane is chosen for comparison because it has been used by the EPA as the informal standard to determine "negligible" reactivity for VOC exemption purposes (Dimitriades, 1999). If a compound does not have a significantly greater impact on ozone than ethane in most or all the scenarios, it might be reasonably be considered for exemption from regulation as

an ozone precursor. Acetone is also shown for comparison because it is a compound of comparable reactivity that has already been exempted.

Table 5 shows that the change in methyl pivalate's mechanism made in this work relative to the one used by Carter (2000) causes only a small change in its calculated atmospheric reactivity, with the new values being approximately $3 \%$ less than those given by Carter (2000). This is well within the uncertainty of any of these reactivity calculations.

The results show that methyl pivalate is a relatively low impact on ozone formation compared to the mixture used to represent reactive VOC emissions from all sources. On a mass basis, its effect on peak $\mathrm{O}_{3}$ is only $10-20 \%$ that of this mixture depending on $\mathrm{NO}_{\mathrm{x}}$ conditions, with the lowest relative impacts being in the higher $\mathrm{NO}_{\mathrm{x}}$ conditions that are most sensitive to VOC controls. The effect of methyl pivalate on the maximum 8-hour average ozone is about $10 \%$ that of the base ROG, with less dependence on $\mathrm{NO}_{\mathrm{x}}$ conditions. This means that regulating methyl pivalate emissions is only about $10-20 \%$ as effective in reducing ozone as is regulating emissions from all VOC sources.

The results also show that the incremental reactivities of methyl pivalate, acetone, and ethane are very similar. Although the averages for methyl pivalate are slightly higher than those for ethane, the differences are probably not significant given the $30 \%$ uncertainty in relative reactivity estimates even for compounds with relatively well established mechanisms, and given the variability of reactivities with environmental conditions. For example, Wang et al (2000) estimate the relative MIR's for methane, nbutane, and methanol are in the $30-35 \%$ range, suggesting that the same should be the case for ethane. An indication of the scenario-to-scenario variability of the reactivities of these compounds can be obtained from the reactivity data on Table 5 and Table 6.

Another indication of scenario-to-scenario variability in relative reactivities of methyl pivalate, ethane, and acetone is given on Figure 3, which shows distribution plots of the relative ozone yield and maximum 8-hour average ozone reactivities for the 39 base case scenarios. It is interesting to note that the distributions in relative reactivities for ethane and methyl pivalate are almost exactly the same, while the relative reactivity of acetone is considerably less dependent on scenario conditions. The differences in the average reactivities of ethane and methyl pivalate are quite small compared to the width of the distributions, and the extent of their overlap.

Figure 3. Distribution plots of relative reactivities of ethane, methyl pivalate, and acetone in the base case scenarios.

## CONCLUSIONS

The decision whether it is appropriate to regulate a compound as an ozone precursor requires a quantitative assessment of its ozone impacts under a variety of environmental conditions. This involves developing a chemical mechanism for the compound's atmospheric reactions that can be reliably used in airshed models to predict its atmospheric reactivity. Until this study, and that of Wallington et al (2000) there was no experimental information concerning the atmospheric reactions of methyl pivalate, and thus reactivity estimates for this compound were highly uncertain. The study of Wallington et al (2000) provided needed data concerning the atmospheric reaction rate of methyl pivalate, and useful information concerning the products formed in this reaction. The objective of this study was to develop a mechanism for the atmospheric reactions of methyl pivalate that is consistent with these data, and to verify whether this mechanism can accurately predict the ozone impacts of this compound under a variety of environmental conditions. We believe this program was successful in achieving this objective.

The methyl pivalate atmospheric reaction mechanism developed in this work was found to give sufficiently good simulations of the effects of methyl pivalate on NO oxidation, $\mathrm{O}_{3}$ formation and other manifestations of reactivity that it should serve as a reliable basis for estimating its ozone impacts in the atmosphere. The mechanism is consistent with the kinetic and product data of Wallington et al (2000), and although the mechanism incorporates some uncertain estimates concerning some of its details, the only adjustments made to optimize fits to the chamber data concerned relatively small changes to the overall nitrate yields that are well within the uncertainty of the estimation methods. Therefore, the mechanism is considered to be consistent with our current knowledge of atmospheric chemistry as well as having predictive capability.

Based on this mechanism, the ozone impact of methyl pivalate on a mass basis was calculated to be relatively low, with the impacts on peak ozone being between $10-20 \%$ of the mixture representing VOC emissions from all sources, depending on scenario conditions. The average relative impacts on maximum 8-hour average ozone is somewhat lower, being $\sim 10 \%$ that of the base ROG mixture, with less dependence on conditions. The mass-based ozone impacts were found to be essentially the same as those for ethane, at least to within the uncertainty of atmospheric reactivity calculations and considering the variability of ozone impacts with atmospheric conditions, and very similar to those for acetone. Since ethane has served as the informal standard in regard to deriving "negligible" reactivity for VOC exemption purposes, and since acetone has already been exempted on this basis, these results suggest that exempting methyl pivalate on the same basis may also be appropriate.

## APPENDIX A. <br> MECHANISM LISTING AND TABULATIONS

This Appendix gives a complete listing of the mechanisms used in the model simulations in this report. Table A-1 contains a list of all the model species used in the mechanism, and Table A-2 lists the reactions and rate parameters, and Table A-3 lists the absorption cross sections and quantum yields for the photolysis reactions. In addition, Finally, Table A-4 gives the chamber-dependent parameters used in the model simulations of the chamber experiments.

Table A-1. Listing of the model species in the mechanism used in the model simulations discussed in this report.

Type and Name Description

## Species used in Base Mechanism

Constant Species.

| O2 | Oxygen |
| :--- | :--- |
| M | Air |
| H2O | Water |
| H2 | Hydrogen Molecules |
| HV | Light |

Active Inorganic Species.

| O3 | Ozone |
| :--- | :--- |
| NO | Nitric Oxide |
| NO2 | Nitrogen Dioxide |
| NO3 | Nitrate Radical |
| N2O5 | Nitrogen Pentoxide |
| HONO | Nitrous Acid |
| HNO3 | Nitric Acid |
| HNO4 | Peroxynitric Acid |
| HO2H | Hydrogen Peroxide |
| CO | Carbon Monoxide |
| SO2 | Sulfur Dioxide |

Active Radical Species and Operators.

| HO. | Hydroxyl Radicals |
| :--- | :--- |
| HO2. | Hydroperoxide Radicals |

C-O2. Methyl Peroxy Radicals
RO2-R. Peroxy Radical Operator representing NO to NO2 conversion with HO2 formation.
R2O2. Peroxy Radical Operator representing NO to NO2 conversion without HO2 formation.
RO2-N. Peroxy Radical Operator representing NO consumption with organic nitrate formation.
CCO-O2. Acetyl Peroxy Radicals
RCO-O2. Peroxy Propionyl and higher peroxy acyl Radicals
BZCO-O2. Peroxyacyl radical formed from Aromatic Aldehydes
MA-RCO3. Peroxyacyl radicals formed from methacrolein and other acroleins.
Steady State Radical Species
O3P Ground State Oxygen Atoms
O*1D2 Excited Oxygen Atoms
TBU-O. t-Butoxy Radicals
BZ-O. Phenoxy Radicals
BZ(NO2)-O. Nitro-substituted Phenoxy Radical
HOCOO. Radical formed when Formaldehyde reacts with HO2

| PAN and PAN Analogues |  |  |
| :--- | :--- | :---: |
| PAN | Peroxy Acetyl Nitrate |  |
| PAN2 | PPN and other higher alkyl PAN analogues |  |
| PBZN | PAN analogues formed from Aromatic Aldehydes |  |
| MA-PAN | PAN analogue formed from Methacrolein |  |

Explicit and Lumped Molecule Reactive Organic Product Species

Table A-1 (continued)

| Type and Name | Description |
| :---: | :---: |
| НСНО | Formaldehyde |
| CCHO | Acetaldehyde |
| RCHO | Lumped C3+ Aldehydes |
| ACET | Acetone |
| MEK | Ketones and other non-aldehyde oxygenated products that react with OH radicals slower than $5 \times 10^{-12} \mathrm{~cm}^{3}$ molec $^{-2} \mathrm{sec}^{-1}$. |
| MEOH | Methanol |
| COOH | Methyl Hydroperoxide |
| ROOH | Lumped higher organic hydroperoxides |
| GLY | Glyoxal |
| MGLY | Methyl Glyoxal |
| BACL | Biacetyl |
| PHEN | Phenol |
| CRES | Cresols |
| NPHE | Nitrophenols |
| BALD | Aromatic aldehydes (e.g., benzaldehyde) |
| METHACRO | Methacrolein |
| MVK | Methyl Vinyl Ketone |
| ISO-PROD | Lumped isoprene product species |
| Lumped Parameter Products |  |
| PROD2 | Ketones and other non-aldehyde oxygenated products that react with OH radicals faster than $5 \times 10^{-12} \mathrm{~cm}^{3} \mathrm{molec}^{-2} \mathrm{sec}^{-1}$. |
| RNO3 | Lumped Organic Nitrates |
| Uncharacterized Reactive Aromatic Ring Fragmentation Products |  |
| DCB1 | Reactive Aromatic Fragmentation Products that do not undergo significant photodecomposition to radicals. |
| DCB2 | Reactive Aromatic Fragmentation Products which photolyze with alpha-dicarbonyl-like action spectrum. |
| DCB3 | Reactive Aromatic Fragmentation Products which photolyze with acrolein action spectrum. |
| Non-Reacting Species |  |
| CO 2 | Carbon Dioxide |
| XC | Lost Carbon |
| XN | Lost Nitrogen |
| SULF | Sulfates ( $\mathrm{SO}_{3}$ or $\mathrm{H}_{2} \mathrm{SO}_{4}$ ) |
| Low Reactivity Compounds or Unknown Products Represented as Unreactive |  |
| H2 | Hydrogen |
| HCOOH | Formic Acid |
| CCO-OH | Acetic Acid |
| RCO-OH | Higher organic acids |
| CCO-OOH | Peroxy Acetic Acid |
| RCO-OOH | Higher organic peroxy acids |
| NROG | Unspecified Unreactive Carbon |

Table A-1 (continued)

| Type and Name | Description |
| :---: | :---: |
| Base ROG VOC Species and Test Compounds Used in the Chamber Simulations |  |
| N-C4 | n-Butane |
| N-C6 | n -Hexane |
| N-C8 | n-Octane |
| ETHENE | Ethene |
| PROPENE | Propene |
| T-2-BUTE | Trans-2-Butene |
| TOLUENE | Toluene |
| M-XYLENE | m -Xylene |
| ME-PVAT | Methyl Pivalate |
| Explicit and Lumped VOC Species used in the Ambient Simulations |  |
| Primary Organics Represented explicitly |  |
| CH4 | Methane |
| ETHENE | Ethene |
| ISOPRENE | Isoprene |
| Example Test VOCs not in the Base Mechanism |  |
| ETHANE | Ethane |
| Lumped Parameter Species |  |
| ALK1 | Alkanes and other non-aromatic compounds that react only with OH , and have $\mathrm{kOH}<5$ $\times 10^{2} \mathrm{ppm}-1 \mathrm{~min}-1$. (Primarily ethane) |
| ALK2 | Alkanes and other non-aromatic compounds that react only with OH , and have kOH between $5 \times 10^{2}$ and $2.5 \times 10^{3} \mathrm{ppm}-1 \mathrm{~min}-1$. (Primarily propane and acetylene) |
| ALK3 | Alkanes and other non-aromatic compounds that react only with OH , and have kOH between $2.5 \times 10^{3}$ and $5 \times 10^{3} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| ALK4 | Alkanes and other non-aromatic compounds that react only with OH , and have kOH between $5 \times 10^{3}$ and $1 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| ALK5 | Alkanes and other non-aromatic compounds that react only with OH , and have kOH greater than $1 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| ARO1 | Aromatics with $\mathrm{kOH}<2 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| ARO2 | Aromatics with $\mathrm{kOH}>2 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| OLE1 | Alkenes (other than ethene) with $\mathrm{kOH}<7 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| OLE2 | Alkenes with $\mathrm{kOH}>7 \times 10^{4} \mathrm{ppm}-1 \mathrm{~min}-1$. |
| TERP | Terpenes |

Table A-2. Listing of the reactions in the mechanism used in the model simulations discussed in this report. See Carter (2000) for documentation.

$$

[a] Except as indicated, the rate constants are given by $k(T)=A \cdot(T / 300)^{B} \cdot e^{-E / R T}$, where the units of $k$ and A are $\mathrm{cm}^{3}$ molec $^{-1} \mathrm{~s}^{-1}$, Ea are kcal mol ${ }^{-1}$, T is ${ }^{\circ} \mathrm{K}$, and $\mathrm{R}=0.0019872 \mathrm{kcal} \mathrm{mol}^{-1} \mathrm{deg}^{-1}$. The following special rate constant expressions are used:
Phot Set = name: The absorption cross sections and quantum yields for the photolysis reaction are given in Table A-5, where "name" indicates the photolysis set used. If a "qy=number" notation is given, the number given is the overall quantum yield, which is assumed to be wavelength independent.
Falloff: The rate constant as a function of temperature and pressure is calculated using $k(T, M)=\{k 0(T) \cdot[\mathrm{M}] /[1$ $+\mathrm{k} 0(\mathrm{~T}) \cdot[\mathrm{M}] / \operatorname{kinf}(\mathrm{T})]\} \cdot \mathrm{F}^{\mathrm{Z}}$, where $\left.\mathrm{Z}=\left\{1+\left[\log _{10}\{\mathrm{k} 0(\mathrm{~T}) \cdot[\mathrm{M}]) / \operatorname{kinf}(\mathrm{T})\right\}\right]^{2}\right\}^{-1},[\mathrm{M}]$ is the total pressure in molecules $\mathrm{cm}^{-3}, \mathrm{~F}$ is as indicated on the table, and the temperature dependences of k 0 and kinf are as indicated on the table.
(Slow): The reaction is assumed to be negligible and is not included in the mechanism. It is shown on the listing for documentation purposes only.
$\underline{\mathrm{k}=\mathrm{k} 0+\mathrm{k} 3 \mathrm{M}(1+\mathrm{k} 3 \mathrm{M} / \mathrm{k} 2) \text { : The rate constant as a function of temperature and pressure is calculated using }}$ $\mathrm{k}(\mathrm{T}, \mathrm{M})=\mathrm{k} 0(\mathrm{~T})+\mathrm{k} 3(\mathrm{~T}) \cdot[\mathrm{M}] \cdot(1+\mathrm{k} 3(\mathrm{~T}) \cdot[\mathrm{M}] / \mathrm{k} 2(\mathrm{~T}))$, where $[\mathrm{M}]$ is the total bath gas (air) concentration in molecules $\mathrm{cm}^{-3}$, and the temperature dependences for $\mathrm{k} 0, \mathrm{k} 2$ and k 3 are as indicated on the table.
$\mathrm{k}=\mathrm{k} 1+\mathrm{k} 2[\mathrm{M}]$ : The rate constant as a function of temperature and pressure is calculated using
$\mathrm{k}(\mathrm{T}, \mathrm{M})=\mathrm{k} 1(\mathrm{~T})+\mathrm{k} 2(\mathrm{~T}) \cdot[\mathrm{M}]$, where $[\mathrm{M}]$ is the total bath gas (air) concentration in molecules $\mathrm{cm}^{-3}$, and the temperature dependences for k 1 , and k 2 are as indicated on the table.
Same k as Rxn label: The rate constant is the same as the reaction with the indicated label.
[b] Format of reaction listing: "=" separates reactants from products; "\#number" indicates stoichiometric coefficient, "\#coefficient \{ product list \}" means that the stoichiometric coefficient is applied to all the products listed. See Table A-1 for a listing of the model species used.
[c] Best fit or adjusted mechanisms derived as discussed in the text.

Table A-4. Chamber wall effect and background characterization parameters used in the environmental chamber model simulations for mechanism evaluation.

| Cham. Set [a] | Value | Discussion |
| :---: | :---: | :---: |
| $\underline{\mathrm{RN}-\mathrm{I}}$ (ppb) |  | Ratio of the rate of wall + hv-> HONO to the $\mathrm{NO}_{2}$ photolysis rate. |
| DTC 18 | 0.066 | Average of value of RS-I that gave best fits to n-butane - NOx chamber experiments carried out in this chamber. The initial HONO was optimized at the same time. If a temperature dependence is shown, it was derived from the temperature dependence of the RN-I values that best fit characterization data in outdoor chamber experiments, with the same activation energy used in all cases. If a temperature dependence is not shown, then the temperature variation for experiments in this set is small compared to the run-to-run variability in the best fit RN-I values. Note that the radical source in Sets 3, 12, 13, and 16 runs was anomalously high. Any dependence of apparent radical source on initial NOx levels in Teflon bag chambers was found to be much less than the run-to-run variability. |
| HONO-F (unitless) |  | Ratio of the initial HONO concentration to the measured initial NO2. [The initial NO2 in the experiment is reduced by a factor of $1-(\mathrm{HONO}-\mathrm{F})$ ]. Unless the characterization data indicate otherwise, it is assumed that the initial HONO is introduced with the NO2 injection, so is it is assumed to be proportional to the initial NO 2 concentration. |
| DTC 18 | 0.8\% | Average of value of initial HONO to initial NO2 that gave best fits to nbutane - NOx chamber experiments carried out in this chamber. The RN-I parameter was optimized at the same time. |
| E-NO2/K1 (ppb) |  | Ratio of rate of NO2 offgasing from the walls to the NO 2 photolysis rate. |
| All Teflon Bag Chambers | 0 | The NOx offgasing caused by representing the radical source by HONO offgasing appears to be sufficient for accounting for NOx offgasing effects in most cases. RN-I parameters adjusted to fit experiments sensitive to the radical source are consistent with NOx offgasing rates adjusted to fit pure air or aldehyde - air runs, to within the uncertainty and variability. |
| $\underline{\mathrm{k}(\mathrm{NO} 2 \mathrm{~W})\left(\mathrm{min}^{-1}\right)}$ |  | Rate of unimolecular loss (or hydrolysis) of NO2 to the walls. |
| All Teflon Bag Chambers | 1.6e-4 | Based on dark NO2 decay and HONO formation measured in the ETC by Pitts et al. (1984). Assumed to be the same in all Teflon bag chambers, regardless of volume. |
| YHONO |  | Yield of HONO in the unimolecular reaction (hydrolysis) of NO2 on the walls. |
| All Teflon Bag Chambers | 0.2 | Based on dark NO2 decay and HONO formation measured in the ETC by Pitts et al. (1984). Assumed to be the same in all Teflon bag chambers, regardless of volume. |
| $\underline{\mathrm{k}(\mathrm{O} 3 \mathrm{~W})\left(\mathrm{min}^{-1}\right)}$ |  | Unimolecular loss rate of O3 to the walls. |
| DTC All | $1.5 \mathrm{e}-4$ | Based on results of $\mathrm{O}_{3}$ decay in Teflon bag chambers experiments as discussed by Carter et al (1995c). |
| $\underline{\mathrm{k}(\mathrm{N} 26 \mathrm{I})\left(\mathrm{min}^{-1}\right)}$ |  | Rate constant for $\mathbf{N} 2 \mathrm{O5}$-> 2 Wall-NOx. This represents the humidityindependent portion of the wall loss of $\mathrm{N}_{2} \mathrm{O}_{5}$, or the intercept of plots of rates of $\mathrm{N}_{2} \mathrm{O}_{5}$ loss against humidity. |
| All Teflon Bag Chambers | 2.8e-3 | Based on $\mathrm{N}_{2} \mathrm{O}_{5}$ decay rate measurements made by Tuazon et al (1983) for the ETC. Assumed to be independent of chamber size (Carter et al, 1995c). |

Table A-4 (continued)

| Cham. Set [a] | Value | Discussion |
| :---: | :---: | :---: |
| $\underline{\mathrm{k}(\mathrm{N} 26 \mathrm{~S})\left(\mathrm{ppm}^{-1} \mathrm{~min}^{-1}\right)}$ |  | Rate constant for $\mathbf{N 2 O 5}+\mathbf{H 2 O}$-> $\mathbf{2}$ Wall-NOx. This represents the humidity dependent portion of the wall loss of $\mathrm{N}_{2} \mathrm{O}_{5}$, or the slope of plots of rates of $\mathrm{N}_{2} \mathrm{O}_{5}$ loss against humidity. |
| All Teflon Bag Chambers | 1.1e-6 | Based on $\mathrm{N}_{2} \mathrm{O}_{5}$ decay rate measurements made by Tuazon et al (1983) for the ETC. Assumed to be independent of chamber size (Carter et al, 1995d). |
| $\underline{\mathrm{k}(\mathrm{XSHC})\left(\mathrm{min}^{-1}\right)}$ |  | Rate constant for $\mathbf{O H}$-> HO2. This represents the effects of reaction of OH with reactive VOCs in the background air or offgased from the chamber walls. This parameter does not significantly affect model simulations of experiments other than pure air runs. |
| All Teflon Bag Chambers | 250 | Estimated from modeling several pure air in the ITC (Carter et al, 1996c), and also consistent with simulations of pure air runs in the ETC (Carter et al, 1997a). |
| $\underline{\mathrm{H} 2 \mathrm{O}}$ (ppm) |  | Default water vapor concentration for runs where no humidity data are available. |
| DTC all | $1.0 \mathrm{e}+3$ | Experiments in this chamber were carried out using dried purified air. The limited humidity data for such runs indicate that the humidity was less than $5 \%$, probably no more than $\sim 2.5 \%$, and possibly much less than that. The default value corresponds to $\sim 2.5-3 \% \mathrm{RH}$ for the conditions of most experiments. |

[a] Set refers to the characterization set, which refers to the group of experiments assumed to have the same run conditions and represented using the same chamber-dependent parameters. See Carter et al (1995) for more discussion. All experiments in this program were in DTC characterization set 18.

[^0]:    ${ }^{1}$ The error was due to using an incorrect branching ratio for the products of the methyl acetate +OH reactions when deriving the estimate. This significantly affects only estimates for methyl esters, where

[^1]:    ${ }^{2}$ Note that this differs from how the term "incremental reactivity" is used in the context of chamber experiments. In that case, the incremental reactivity refers to the relative change observed in the individual experiments, which in general depends on the amount added.
